Sugars, particularly the disaccharides, are the most often cited stabilizers used in lyophilized protein formulations. The two hypotheses put forth for describing the efficacy of disaccharides in stabilizing proteins are the water replacement and glassy state models. The water replacement hypothesis postulates that disaccharides stabilize dried proteins through "hydration" at sites previously occupied by water [269]. The glassy state hypothesis suggests that protein stabilization is the result of increased glass transition temperature [270]. It should be noted that the most commonly used disaccharides, sucrose and trehalose, have been reported to demonstrate varying degrees of protection, depending on the protein and the protein-to-disaccharide ratio [271,272]. The excipients that can act as water substitutes often allow for a reduction in residual water content. In addition, many of these excipients (e.g., mannitol) are required to produce a dry cake of high quality and are often included to produce a uniform powder that can easily be reconstituted. In many formulations, salts are added to control the osmolality of the solution. However, lyophilization in the presence of salts such as sodium chloride has caused several proteins to precipitate [273,274]. The effect of sodium chloride on the freezing process (freezing point depression) may result in aggregation [72] or increased binding to the protein [275]. To circumvent these issues, mannitol or other sugars are often used as isotonicifiers. In addition, non-ionic surfactants, such as polysorbates, are commonly included in formulations to prevent stresses related to freeze–thaw cycles, presumably by inhibiting denaturation at the ice–water interface [170].

The residual water content of the freeze-dried cake has been reported to have a significant impact on the structure and stability of the dried protein. Several studies have suggested the existence of an optimum residual water content required to maintain the stability of various protein formulations [276]. After determining the

optimum level, the maintenance of this water content becomes critical to the stability of the dried formulation.

Dried protein products generally require a reconstitution step before administration. Such a step could lead to different levels of protein degradation, depending on the reconstitution procedure, reconstitution medium, and presence of other excipients. It is generally recommended that reconstitution be conducted carefully, not to create any air bubbles. In this regard, high vacuum in the product container should be avoided to allow adequate control of the reconstitution medium stream in contact with the inside wall of the product container. Inclusion of a protein stabilizer in the reconstitution medium has been reported to minimize protein degradation [277].

In addition to the factors already described, problems can be encountered during process scale up. Factors that introduce heterogeneity between the vials need to be optimized. Furthermore, differences in heat and mass transfer between laboratory-scale, pilot-scale, and production-scale lyophilizers need to be taken into account.

Besides freeze-drying, several other processes are available to remove water from the protein formulation, including spray drying [278,279], spray freeze-drying [280,281], vacuum drying [282,283], and foam drying [284,286], to name a few. These are not commonly used due to various operational and scale-up challenges.

***11.3.2.6 Storage, Transport, and Delivery*** Filled vials are crimped and inspected. Appropriate inspection criteria need to be in place for both liquid and solid dosage forms. Liquid dosage forms should be inspected for particulate matter. Inspection methods can vary from manual (i.e., visual) to the use of automated machines. An allowable reject ion rate for inspection should be established. Following inspection, the vials are labeled and packaged. These steps, combined with inspection (both manual and automated), typically result in the exposure of DP to light for a prolonged period of time. Photoexposure could affect product quality, so it should be evaluated a priori for the worst-case conditions (maximum intensity and duration).

Unexpected environmental changes can be encountered during distribution and handling of products, including accidental freezing, exposure to temperatures outside of the recommended range, and vigorous agitation. It is critical to develop the formulation with these stresses in mind because product quality can be compromised.

Container closure systems could be a major factor in influencing the activity and immunogenicity of the protein DP [266]. After DP fill-finish operations are complete, they need to be transferred either to various storage sites or to the clinic. Transportation-related stresses include those that are related to vibration, shock, and changes in pressure and temperature, which might be experienced during air or ground transportation. When protein solutions are moved or vibrated during shipping or mixing, proteins are subjected to certain degrees of shaking stress. Exposure to light could induce protein oxidation, as discussed earlier. The International Conference on Harmonization (ICH) Q1B guideline recommends performing photostability testing in a controlled light chamber. It is likely that biologics, given their nature, may fail the recommended levels specified in ICH Q1B. However, it is possible that

formulation components, such as antioxidants, may slow down the rate and extent of photodegradation. A time-dependence study would need to be designed to test the resilience of the biologic to light-induced degradation. From this study, recommendation could be made in regards to processing times and light exposure conditions during manufacture, transport, and storage.

## 11.4 SUMMARY

Protein instability encompasses many complicated, as well as interrelated, chemical and physical processes. Destabilization can occur during any of the fill-finish operations described in this chapter (see Fig. 11.1). Even with the advancements in the development of protein pharmaceuticals, several unmet needs still remain. Of them, two stand out: high-concentration formulations and high-throughput analytics.

For products that require frequent and chronic administration, the SC route of administration is preferred. In particular, when coupled with the use of prefilled syringe and autoinjector device technology, SC delivery allows for self-administration and improved patient compliance, which may result in expansion of product market. Treatment with high doses may require development of formulations at concentrations exceeding 100 mg/ml because of the small volume limited by the SC route of administration. Development of formulations at high concentrations also poses stability, manufacturing, and delivery challenges; for example, increasing protein concentration may lead to higher viscosity, which may be difficult to administer by injection [48]. The other alternative is the delivery of higher volumetric dose.

Aggregation is expected to be the primary degradation pathway in high-concentration protein formulations. However, the relationship among concentration, rate, and extent of aggregate formation depends highly on the mechanism of association [287]. In contrast, many of the chemical reactions, such as deamidation, Asp isomerization, and oxidation, generally demonstrate kinetics that follow lower order concentration dependency. Macromolecular crowding (i.e., excluded volume effects) can also affect the physical properties of proteins, such as viscosity, which can impact the capability to manufacture high-concentration formulations.

Although it may be possible to create a formulation that demonstrates the desired stability profile during development, the design of processes to allow large-scale manufacture is critical and cannot be postponed. Two commonly used processes at large scale are tangential flow filtration (TFF) and lyophilization. TFF is the main technology for buffer exchange and concentration of proteins that have been used at commercial scale [288,289]. The main problem that has been identified during processing is the shear sensitivity of the protein, which may lead to the formation of aggregates and particulates during filling of the final product. Another parameter that could limit the use of a TFF system to concentrate a protein solution is its high viscosity. Although TFF is the industry standard for concentrating macromolecules at large scale, there are alternatives. High-concentration protein formulation can be achieved either by decreasing the solvent content while retaining the protein (e.g., using TFF) or by removal of the solvent (i.e., drying) followed by reconstitution with

reduced solvent volume. Bulk-drying processes include spray drying [278], fluid bed drying [290], vacuum drying [283], and lyophilization in tray units [291]. For parenteral protein products, bulk-drying processes require operation under aseptic conditions. As the protein-loading concentration is increased, reconstitution occurs much more slowly. Investigation of the morphology of the lyophilized solid by scanning electron microscopy has revealed a very dense compact structure at 110 mg/ml compared with a loosely packed layer of flakes at 40 mg/ml [292].

Although high-concentration formulations have the cost saving advantage of decreasing bulk storage space or number of product fills, they suffer from undesirable overall cost of goods caused by unrecoverable volumes from various product-contacting surfaces and containers. The loss could be minimized by decreasing product contact surface areas, such as with the use of smaller or narrower based vials or a prefilled syringe, in which the solution can be pushed off the surface with the plunger head.

Generally, analytical techniques used to characterize proteins involve either dilution to lower concentrations or exposure of protein to solvent conditions that are drastically different from the initial formulation composition. This may have considerable impact on the results of the assay because change in solvent composition or concentration may alter the physical state of the protein, resulting in a non-representative sample. Technologies such as static and dynamic light scattering [293,294] and analytical ultracentrifugation [295,296] provide more representative information about the self-association states of proteins at high concentrations due to the maintenance of the sample concentration during analysis.

With the number of monoclonal antibody candidates increasing (with compressed timelines for their development), there is a strong need for high-throughput analytical methods. A common high-throughput formulation development (HTFD) format is the use of commercially available multiwell microplates [297]. These can be placed in automated liquid-processing systems for sample preparation, dispensing, and handling. The low sample volume required for analysis can potentially save a large amount of protein DS. The HTFD microplate format is especially useful for the rapid screening of protein aggregation through turbidity measurement because this can be conveniently and non-invasively analyzed using a spectrophotometer [298]. It should be noted, however, that the small sample volume in microplates may not be sufficient to allow for a detailed analysis of other degradation pathways by traditional analytical methods, and protein surface adsorption and evaporation may contribute significantly to the variations in the results. There is certainly more development to come in this field.

# Regulatory Strategies and Lessons in the Development of Biosimilars

UMANG S. SHAH

## 12.1 BACKGROUND AND OBJECTIVE

In 1982, human insulin was introduced as the first recombinant-derived therapeutic protein (cloned by Genentech scientists and licensed to Eli Lilly and Company). Since then, more than 200 different lifesaving or greatly improving "quality of life" protein drugs have been introduced, and this class of therapeutics has become firmly established [1]. However, protein therapeutics are typically very expensive compared with small molecule drugs (one study has stated that the average biologic is about 22 times more expensive than the average small molecule innovative drug) [2]. A year's worth of breast cancer–fighting Herceptin, a biopharmaceutical, for example, averages $54,000; Cerezyme for treating a rare disorder known as Gaucher disease costs around $200,000 a year; a Enbrel for rheumatoid arthritis averages more than $19,000 a year [3]. A more affordable version of such protein therapeutic could result in the possibility of utilization and accessibility to a larger population of patients as well as cost savings to patients, insurance companies, and federal budgets. The first phase of the first generation of modern biotechnology-derived protein drugs is coming to an end with the expiration of their patents (Table 12.1), and an ongoing debate about the scientific and regulatory issues associated with the development of generic (i.e., follow-on) protein therapeutics has emerged and is continuously evolving. The term "generic" protein therapeutics is not a common term used by the scientific community, the US Food and Drug Administration (FDA), or the European Medicines Agency (EMA) for such molecules, and these molecules are typically referred to as biosimilars, reflecting the difficulties in their manufacture,

characterization, and comparison with a reference innovator product. In Europe, the EMA has passed guidelines for the abbreviated approval of biosimilars and has even approved several small, simple, and less complex biopharmaceuticals. In the United States, efforts to create regulatory pathways for similar versions of biopharmaceuticals have been fraught with scientific, political, and financial issues. After extensive debate about creating a formal regulatory pathway for biosimilars, the most recent proposal appears to be similar to the 505(b)(2) drug approval process. On March 23, 2010, President Obama signed into law a reconciliation bill that finalizes Congress's health care reform legislation, the Patient Protection and Affordable Care Act. Now after years of public debate, biosimilars and interchangeable biological products are closer to becoming reality for patients in the United States as President Obama's health care reform bill amends the Public Health Service Act (PHSA) to strike a balance between "innovation and consumer interest" because in addition to the much-discussed provisions regarding health insurance, this act creates a regulatory pathway for biosimilars [4]. Passage of the PHSA has resulted in the FDA's considering standards to govern authorization for marketing of biosimilars and interchangeables. The FDA released three draft guidances on implementation of the Biologics Price Competition and Innovation Act in February 2012. These are:

1. Biosimilars: Questions and Answers Regarding Implementation of the Biologics Price Competition and Innovation Act of 2009
2. Quality Considerations in Demonstrating Biosimilarity to a Reference Protein Product
3. Scientific Considerations in Demonstrating Biosimilarity to a Reference Product

Although these guidances create new and different standards, they also raise new barriers to entry in their definitions of data exclusivity and patent litigation procedures.

The objective of this chapter is to understand the scientific challenges and the main elements of the EU pathway and the proposed US FDA regulatory pathway for biosimilars while considering potential strategies in the development of a successful biosimilar.

## 12.2 HISTORY

Over the past several decades, biomedical research has enhanced our understanding of molecular principles of health and diseases and resulted in revealing many polypeptides that possess significant medicinal potential. In the 1970s, the development of two new techniques—recombinant DNA technology (genetic engineering) and monoclonal antibody (mAb) technology (hybridoma technology; Drs César Milstein and Georges Köhler of the MRC Laboratory)—marked the birth of the modern biotech era [5].

Recombinant DNA technology has fourfold impact on production of pharmaceutically important proteins:

1. Overcomes the problem of source availability
2. Overcomes problems of product safety (direct extraction may unwittingly transmit diseases such as hepatitis B or C and HIV)
3. Provides an alternative to direct extraction from inappropriate or dangerous source material (e.g., fertility hormone follicle-stimulating hormone obtained from the urine of postmenopausal women and a related hormone, human chorionic gonadotropin, from urine of pregnant woman, and Ancrod, an anticoacoa extracted from Malaysian pit vipers)
4. Facilitates generation of engineered therapeutic proteins displaying clinical advantage over native proteins (site-directed mutagenesis facilitates predefines changes, e.g., slow- and fast-acting insulins, chimeric or humanized antibodies greatly reduce immunogenicity)

## 12.3 MARKET

The advent of the aforementioned two breakthrough technologies underpinned the establishment of start-up biopharmaceutical companies in the 1980s founded by academic and technical experts and financed by venture capitalists. By mid 2002, about 120 biopharmaceutical products gained marketing approval in the United States or European Union, representing a market share of $15 billion. The sales of biopharmaceuticals reached $20 billion in 2003, and by 2007, worldwide sales reached US $94 billion, accounting for about 15.56% of the pharmaceutical industry's gross revenue. From 2000 to 2006, biopharmaceuticals accounted for 33% of all new active substances that were launched and are reflected to a similar degree in the current development pipelines of the pharmaceutical industry. The sales of the top 10 biologic brands increased significantly in 2011. The market leader was Humira with sales of $7.9 billion followed by Enbrel and Remicade. Drug products such as epoetin-α (Epogen, Eprex, Procrit), abciximab (ReoPro), interferon-α (Intron A, Roferon A), interferon-β (Avonex, Rebif, Betaseron), anti–tumor necrosis factor α agents (Enbrel, Remicade, Humira), and trastuzumab (Herceptin) are all examples of highly successful biotech drugs that revolutionized the pharmacotherapy of previously unmet medical needs (see Table 12.1 for first-in class biopharmaceuticals) [6].

EuropaBio (www.europabio.org) reports that by 2007, more than 325 million patients had benefited from approved medicines manufactured through biotechnology and gene technology.

Prevenar was the first vaccine to have sales of $2.7 billion in 2008 and revived the current interest in vaccines. The sales of the biopharmaceutical brands continued to increase significantly through 2009 (Table 12.2). The top 30 biologics sales exceeded $24 billion in 2011 [7]. Among the various segments, vaccines and mAb-based products represent the two biggest product categories followed by regulatory factors

**TABLE 12.2 Top Five Biopharmaceuticals by US Sales (2011)**

| Product | Active Substance | Molecular Weight (Da) | Indications | Company | Approval Date | Worldwide Sales, mm (USD, 2009) |
|---|---|---|---|---|---|---|
| Humira | Adalimumab | ~148,000 | Rheumatoid arthritis, psoriasis, Crohn's disease, ulcerative colitis, psoriatic arthritis | Abbott and Eisai | December 31, 2002 | 7932 |
| Enbrel | Etanercept dimeric fusion protein | ~150,000 | Rheumatoid arthritis, psoriatic arthritis plaque psoriasis | Immunex* | November 2, 1998 | 7867 |
| Remicade | TNF-α antagonist | ~149,100 | Rheumatoid arthritis | Centocor (J&J) | August 24, 1998 | 7157 |
| Rituxan | Rituximab | | Non–Hodgkin's lymphoma | Roche | November 26, 1997 | 6859 |
| Avastin | VEGF | | Metastatic colorectal cancer | Roche | February 26, 2004 | 5813 |

(e.g., hormones and cytokines) and gene therapy and antisense-based products. mAbs began to reveal their full potential in 1986, when Medical Research Council researcher Dr. Gregory Winter pioneered a technique to humanize mouse mAbs [6] because they were much less likely to elicit an inappropriate immune response in patients. Dr. Gregory founded the Cambridge Antibody Technology, which licensed the technique to more than 50 companies worldwide. Subsequently, Humira became the first fully human mAb drug launched in 2003 as a treatment for rheumatoid arthritis. Cambridge Antibody Technology was subsequently acquired by Astra Zeneca in 2006 for £702 million [8].

Some interesting timelines in the mAb landscape include the following:

1975: Method devised to isolate and reproduce mAb
1986: Techniques pioneered to humanize mouse mAb
1990: Test tube production of highly specific human mAb
2003: First fully human mAb, Humira, launched in the United Kingdom
2005: Humira sales reach more than $200 million

Consensus sales forecasts for world's top 10 drugs in 2014 include eight that are of biopharmaceutical origin (Table 12.3).

Opportunities for the biosimilars market are immense because biologics worth $25 billion are going to be off patent by 2016, and the recent approval pathway in the United States will perhaps open up to what is expected to become the largest market [9]. The global biosimilars market is expected to be worth $19.4 billion by 2014,

**TABLE 12.3 Consensus World Sales Forecasts for the Top 10 Drugs in 2014**

| Name (Indication) | Company | Worldwide Sales (US$, billions) |
|---|---|---|
| Avastin* (cancer) | Genentech† | 8.9 |
| Humira* (arthritis) | BASF Pharma‡ | 8.5 |

growing at an expected average annual growth rate of about 89% from 2009 to 2014 [9]. The biosimilar market is also similarly segmented into peptides, recombinant glycosylated proteins, recombinant nonglycosylated proteins, and others. Recombinant nonglycosylated proteins form the largest segment in the biosimilars market, with an estimated $11.5 billion in sales by 2014 [9].

Several biosimilars have already been approved in the European Union under EMA biosimilars regulations and guidelines, including human growth hormone (hGH) Omnitrope and Valtropin and erythropoietins Binocrit, epoetin alfa HEXAL, Abseamed, Silapo, and Retacrit. In the United States, several follow-on versions of protein therapeutics originally approved under the FDC Act have gained approval under Section 505(b)(2), including Omnitrope. However, until March 2010, the approvals in the United States were limited to the original products approved under the FDC Act, not the majority of protein therapeutics approved under the PHSA.

## 12.4 WHY ARE BIOPHARMACEUTICALS DIFFERENT FROM SMALL MOLECULES?

Traditional pharmaceuticals are low-molecular-weight chemicals and are typically manufactured by direct synthesis. Biopharmaceuticals, in contrast, are typically large, complex, heterogeneous, protein-based molecules produced by a living cell–based system that cannot be fully characterized by analytical methods in the laboratory [10]. The differences in production, molecular size, and complexity between chemical medicines and biopharmaceuticals pose the question of whether or not the established legal and regulatory standards for approval of generic medicines, whose very basis is one of sameness or identicality, could be applied to attempted copies of innovator biopharmaceuticals (Table 12.4).

Following are some important considerations for biopharmaceutical products [11]:

- Patient safety: Because of differences between biopharmaceuticals, challenging issues exist relating to the development, approval, and marketing of biosimilar products. Patient safety must be of paramount consideration when evaluating these issues.
- Need for clinical trials and indication-specific approval: Because of the complexity of biopharmaceuticals as well as the distinctions introduced by differing manufacturing processes, each biosimilar must be shown to be safe and effective on the basis of its own adequate and well-controlled clinical studies.
- No automatic substitution or interchangeability: Differing manufacturing processes mean that each biosimilar is likely to be inherently different from the corresponding innovator biologic. As such, pharmacists should not be allowed to freely substitute the follow-on biologic for the innovator's product.
- Postmarketing risk management plans required: Postmarketing risk management plans must be an essential element of any approval of a biosimilar product.

**TABLE 12.4 Differences Between Small Molecular Weight Drugs and Biopharmaceuticals**

| Small-Molecular-Weight Drugs | Biopharmaceuticals |
|---|---|
| Low molecular weight (<5000 Da) | High molecular weight (>5000 Da)<br>Typically they are 100- to 1000-fold larger molecules |
| Simple chemical structure | Complex three-dimensional structure |
| Bioactivity: defined | Difficult to quantify bioactivity |
| Chemically synthesized: predictable and well defined | Produced by living organism; affected by minor changes<br>*Inherent product variability*<br>Carboxylation<br>O-linked glycosylation<br>N-linked glycosylation<br>Oxidation<br>Amino acid substitution<br>Truncation<br>Aggregation<br>Denaturation<br>Amidation, deamidation, and so on |
| Easy characterization: simple definitive details or standards | Difficult or impossible to fully characterize |
| Synthetically pure | Often heterogeneous |
| Relatively stable | Stability: proteins are inherently unstable molecules and may structurally be damaged by heat, prolonged storage, denaturants, organic solvents, oxygen, pH changes, and other factors, leading to reduction or complete loss of biological activity |
| Impurities: defined standards or specifications | Difficult to define and quantify (viral, bacterial, fungal, TSE) |
| Rarely produce immune response | Prone to eliciting immune response |

TSE: transmissible spongiform encephalopathies.

- Similarity and comparability are distinct concepts: The concepts of similarity and comparability are distinct and must be properly applied to any approval process of a biosimilar product.
- No reliance on trade secret or confidential commercial information: Regulatory agencies should not refer to or rely on innovator trade secrets and confidential commercial information to approve a biosimilar product.

## 12.5 TYPICAL BIOPHARMACEUTICAL MANUFACTURING STEPS AND ANALYTICAL TECHNIQUES FOR CHARACTERIZATION

Almost all biopharmaceuticals on the market are produced by genetic engineering using various recombinant expression systems. Proteins are made by living cells such as bacteria, yeast, plant, or mammalian cells acting as the "manufacturing facility."

The manufacturing of recombinant protein products includes cloning, transfecting, screening for the cells, subcloning and developing this cell further concerning expression yield, growth properties, and so on into a master and working cell bank; growing the recombinant cell in large bioreactor vessels (up to and even exceeding 10,000-l scale) depending on the supply needs; purifying the target protein using a multistep downstreaming process; and finally bringing it into a formulation and device suitable for transport, storage, and application to the patients.

The process runs under strictly controlled, validated conditions in closed systems to assure consistency to avoid any contamination in accordance with good manufacturing process (GMP) requirements. The manufacturing process of protein products has a significant impact on the quality of the final product. Figure 12.1 illustrates a typical platform process used for manufacturing of mAb products [12]. Any variability in the quality of the final product depends on the variability of each process step and variability of the starting materials. Media components used in cell culture processes are known to have an impact on the performance of the production bioreactor. Various examples demonstrate that changes in cell lines, expression systems, bioreactor operating conditions, purification process, or even the use of different syringes and vials can lead to changes in quality attributes (Table 12.5).

**FIGURE 12.1** Illustration of complexity of protein product and processes involved. (a) Structure of a typical monoclonal antibody (mAb) along with sites of heterogeneity. (b) Typical platform process for an mAb. HIC: hydrophobic interaction chromatography.

**TABLE 12.5 Typical Product Quality Attributes for a Biological Product***

| Class | Sample Quality Attributes (Commonly Used Tests) |
|---|---|
| Identity | Primary sequence (peptide map and amino acid sequence analysis), immunogenicity (immunoassay), other indications (IE HPLC, gel electrophoresis) |
| Potency | Potency (cell-based bioassay, gene expression bioassay, ADCC, CDC) |
| General characteristics | Appearance or color (visual), clarity (turbidimetric), subvisible particles, pH (potentiometric), osmolality (freezing point depression), conformation (near or far UV, circular dichroism, spectroscopy, Fourier transform infrared spectroscopy, X-ray crystallography and differential scanning calorimetry), effector function (receptor binding), concentration (UV absorbance) |
| Desired host cell modifications | Glycosylation (monosaccharide composition analysis, oligosaccharide profile, CE, LC—MS, MS/MS, ESI, MALDI-TOF), phosphorylation (peptide mapping with MS) |
| Undesirable host cell modifications | Truncation (SE HPLC, gel electrophoresis, analytical ultracentrifugation (AUC), peptide mapping with MS, RP HPLC), glycation (peptide mapping with MS HPLC), methylation, isomerization (RP HPLC) |
| Desired process modifications | PEGylation (HPLC, CE) |
| Undesirable process modifications (product variants and impurities) | Aggregation (SE-HPLC, gel electrophoresis, light scattering, and AUC), oxidation (peptide mapping with MS), deamidation (cIEF), peptide mapping with MS and cation exchange (CEX-HPLC), C terminal lysine (cIEF, peptide mapping with MS, and CEX-HPLC), C-terminal lysine (cIEF, peptide mapping with MS, and CEX-HPLC) misfolds (RP-HPLC) |
| Host cell–related impurities | Host cell proteins (ELISA), DNA, endotoxin (Limulus Amebocyte Lysate assay) |
| Process-related impurities | Antifoam (compendial), extractables (miscellaneous), leachables (miscellaneous), bioburden (membrane filtration test), pluronic (compendial), protein A (protein A ELISA) |

*This list is nonexhaustive.
ADCC: antibody-dependent cell-mediated cytotoxicity; AUC: analytical ultracentrifugation; CDC: complement dependent cytotoxicity; CE: capillary electrophoresis, CEX: cation exchange; cIEF: capillary isoelectric focusing; ELISA: enzyme-linked immunosorbent assay; ESI: electrospray ionization; HPLC: high-performance liquid chromatography; IE: ion exchange; IEF: isoelectric focusing; LC: liquid chromatography; MALDI: matrix-assisted laser desorption ionization; MS: mass spectrometry; RP: reversed phase; SE: size exclusion; TOF: time of flight; UV: ultraviolet.

Potency can be affected by physicochemical or structural changes. A 20% reduction in sialic acid of a glycoprotein can result in 50% loss in amount of circulating protein [13]. For some mAbs, monitoring carbohydrate heterogeneity throughout product manufacturing and comparability assessment is critical because differentiation sialylation, galactosylation, and fucosylation can affect clinical function, including complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity (ADCC), and antigen binding. Generally, a decrease in core fucose content increases ADCC. However, variations in galactosylation do not affect this activity. The role of glycosylation in mAb efficacy is product dependent; therefore, glycosylation analysis is dictated by the product. Schiestl et al. [13] reported change of the isoform distribution between two sets of batches of Aranesp expiring between November 2008 and April 2011 (Fig. 12.2). They reported that a higher sialylated isoform decreased by an average of 10%, and the less sialylated isoform increased by 3%. However, within each set there was high batch-to-batch consistency. They attributed this change as a consequence of manufacturing process change. Aranesp is an engineered analog of human erythropoietin and differs in amino acid sequence that introduces two additional N-glycosylation sites. The *in vivo* biological activity is known to be dependent on number of sialic acid units per molecule (a result of available sites, completeness of sialylation, and antennarity of the N-glycans).

In the same article, Martin Schiestl et al. [13] also characterized commercial batches of Rituxan with expiration dates from September 2007 to October 2011 using glycan mapping, cation exchange chromatography (CEX), and ADCC *in vitro* bioactivity (Fig. 12.3). For Rituxan, the glycosylation-dependent Fc effector functions are essential contributors to its therapeutic mode of action and clinical efficacy. CEX revealed differences in C-terminal lysine and N-terminal glutamine variants between the 2008 and 2010 batches. The basic variants reduced from 30 to 50% to 10%. The glycan map revealed a threefold increase in unfucosylated G0 glycan, and the corresponding ADCC activity also increased.

**FIGURE 12.2** Comparison of pre- and postchange Aranesp batches measured by capillary zone electrophoresis. (a) Relative content of the individual isoforms of the prechange ($n = 18$) and postchange batches ($n = 4$) batches. (b) Representative electropherograms; peaks are labeled with isoform number.

**FIGURE 12.3** The glycan map revealing a threefold increase in unfucosylated G0 glycan and the corresponding antibody-dependent cellular cytotoxicity (ADCC) activity increase. (a) Acidic vs. basic variants (pre- and postprocess change). (b) Relative % area of basic variants (multiple lots). (c) ADCC potency vs. various lots manufactured pre- and post-manufacturing changes. (d) Relative % area of G0 glycan vs. multiple lots. (e) Increase in unfucosylated G0 glycans attributed to manufacturing process changes. (f) Various glycan isoforms. G = glycan isoforms; GlcNAc = *N*-acetylglucosamine; Man = mannose; Fuc = F = fucose; G0 = $GlcNAc_2Man_3GlcNAc_2$; G0F = $GlcNAc_2Man_3GlcNAc_2Fuc$; Man5 = $Man_5GlcNAc_2$; G2F = $Gal_2GlcNAc_2Man_3GlcNAc_2Fuc$; (1,3)G1F or (1,6)G1F = variants of $GalGlcNAc_2Man_3GlcNAc_2Fuc$.

The same authors [13] also reported that for two batches of Enbrel (expiration dates of 2009 and 2011, respectively) (Fig. 12.4), glycan mapping revealed a decrease from 50 to 30% in the N-glycans G2F, but CEX analysis reported an increase to 40 to 60% from 15 to 30% in the C-terminal lysine variants attributable to manufacturing process changes. Figure 12.4 suggests that batch-to-batch variability is small during routine manufacturing, major shifts in product attributes may occur as a result of manufacturing changes, the variance induced by manufacturing changes establishes "goal posts" that a biosimilar company can used for establishing comparability, and it is apparent that originators are essentially manufacturing biosimilars of their original products [13].

From a regulatory perspective, it is expected that a company will provide some comparability data after any change in manufacturing likely to affect product quality during the development process. Before pivotal trials, these data are required to show that the postchange material is similar enough to allow safety data based on earlier material to be applied to the new material.

The consequence of inadequate comparability data (or illustrating significant changes) is the possibility of having to repeat toxicology and safety studies before continuing the clinical development plan. Changes made during or after the pivotal trial require comparability to ensure both safety and efficacy of the postchange

**FIGURE 12.4** Glycan mapping revealing a decrease from 50 to 30% in the N-glycans G2F; cation exchange chromatography analysis reported an increase to 40 to 60% from 15 to 30% in the C-terminal lysine variants.

material. This leads to either significantly extended pivotal trials or new trials altogether. The extent of the comparability exercise is dictated by not only the timeline in product development when the manufacturing change occurs but also by the nature of the change and the nature of the product. The regulatory importance of appropriate assessment of comparability has resulted in the development of the International Committee for Harmonization (ICH) guideline Q5E, "Comparability of Biotechnological/Biological Products Subject to Changes in Their Manufacturing Process," and the EMA has published two guidelines, titled "Guideline on Comparability of Medicinal Products Containing Biotechnology-Derived Proteins as Drug Substance—Non clinical and Clinical" and "Guideline Comparability of Medicinal Products Containing Biotechnology-Derived Proteins as Active Substance—Quality Issues."

Typically, 20 to 30 unit operations are performed during the manufacture of a protein product; therefore, significant variability in product quality is likely by the time the final stages are reached. Minor changes in the process could lead to major changes in the product. It was often stated that for biopharmaceuticals, "the process is the product" (Table 12.6). Even highly purified proteins never consist of one single molecular entity but are mixtures of many closely related molecular species. It has

**TABLE 12.6 Examples Highlighting the Impact of Processes on Product Quality and Clinical Performance**

*Changes in Manufacturing Process*

- The choice of cell line or expression system affects host-cell impurities, which may act as adjuvants or be directly immunogenic.
- Protein glycosylation may be affected by concentrations of glucose, ammonium ions and hormones, cell culture conditions, and hydrodynamic shear.
- mAb product produced by B-cell hybridoma vs. CHO cell transfectoma has been shown to possess varying levels of C-terminal lysine.
- Medium components manufactured by two different suppliers have been shown to lead to differences in product quality.
- Trace amount of contaminants or impurities have been shown to lead to antibody development against insulin and growth hormone products.
- Purification products have been known to have an impact on the incidence of antisomatotropin molecules (Omnitrope vs. Genotrope).

*Leachables and Extractables on Product Safety and Efficacy*

- Uncoated plunger stoppers from syringes leached vulcanizing agent are speculated to cause increased PRCA with Eprex.
- Residual amounts of tungsten used to create syringe have been known to cause aggregation of two protein therapeutic products.
- Glass surfaces, air–liquid interfaces, and lubricants can mediate protein denaturization; phthalates in plastics and latex rubber may contaminate product and cause allergic reactions and increase immunogenicity.

CHO: Chinese hamster ovary; mAB: monoclonal antibody; PRCA: pure blood red cell aplasia.

been estimated that in an immunoglobulin G (Ig G) molecule, there might theoretically be up to 108 different species considering only a limited number of all possible glycosylation variants [12].

Hence, a second manufacturer aiming to replicate a protein product has to run through an analogous procedure without access to the originator's materials (e.g., cell banks) and information (standard operating procedures). For glycosylated proteins, differences in the glycopattern may significantly influence receptor binding, protein–protein interaction, and pharmacokinetics (PKs) of protein substances. For immunoglobulins, small differences in core fucosylation can lead to big changes in Fcc receptor binding and consequently impact immune effector functions such as ADCC, which is believed to be a major mechanism of action contributing to the potency of many mAbs, particularly in oncologic indications. Differences in protein product characteristics may not be detectable by commonly used analytical characterization (Table 12.7).

## 12.6 GENERICS VERSUS BIOSIMILARS

The debate essentially has been about whether technology exists to create and validate a copy of a product made through complex biological processes; hence, neither the scientific community nor the FDA is comfortable designating a

**TABLE 12.7 Analytical Methods and Their Utility in Characterizing Drug Substance and Drug Product (Partial List)**

| Parameter | Methodology | Utility |
|---|---|---|
| Appearance | Visual, turbidity | Physical stability; container-closure integrity |
| Purity-degradation products and related substances | GPC/SEC-HPLC, RP-HPLC, gel electrophoresis, immunoassays | Relative purity of API and drug product; impurities related to expression system |
| Molecular weight and size | GPC/SEC-HPLC, gel electrophoresis, LC—ESI-MS, MALDI-TOF-MS | Product single molecular weight or polydisperse? |
| pH | Potentiometric assays | Is the product pH labile, or do pH changes affect potency? |
| Primary structure | Amino acid sequencing, N-term degradation, Edman sequencing, peptide mapping | Verifies primary amino acid sequence |
| Secondary structure | CD, 2D-NMR | Help determine overall 3D folding |
| Tertiary structure | Disulfide content or position, CD | Correct folding and integrity of 3D product |
| Agglomeration and aggregation | Subvisual and visual particle size analysis, immunogenicity | Physical stability and immunogenic potential |
| Carbohydrate analysis | RP-HPLC, HPLC—MS, gel electrophoresis, MALDI-MS, ESI-MS | Ensures posttranslational modification and carbohydrate content |
| Water content (lyophilized product) | Karl Fischer, NIR | Indicator of hydrolytic potential |
| Immunogenic potential | Surface plasmon response, ELISA, immunoprecipitation | Positive or negative indicators of immunogenic potential |
| Sterility | Membrane filtration | Microbial contamination from manufacturing operations |
| Bacterial endotoxins | LAL | Processing contaminants and host organism contaminants |

AE: anion exchange; CD: circular dichroism; CE: capillary electrophoresis; ELISA: enzyme-linked immunosorbent assay; ESI: electrospray ionization; GPC: gel permeation chromatography; HPLC: high-performance liquid chromatography; LAL: Limulus amebocyte lysate; MALDI: matrix-assisted laser desorption ionization; MS: mass spectrometry; NIR: near infrared; NMR: nuclear magnetic resonance; RP: reversed phase; SEC: size exclusion chromatography; TGA: thermogravimetric analysis; 2D: two-dimensional; 3D: three-dimensional.

biogeneric as a substitutable replacement for the innovator product. Hence, these molecules are typically referred to as biosimilars, reflecting the difficulties in their manufacture, characterization, and comparison with a reference innovator product. Compared with the manufacture of small molecule entities, the manufacture of biopharmaceuticals requires a greater number of batch records (>250 vs. <10), a large number of product quality tests (>2000 vs. <100), an increased amount of

critical process steps (>5000 vs. <100), and significantly larger process data entries (>60,000 vs. <4000) [11]. The molecular weight of a traditional small molecule drug can be measured accurately within 1/100 Da. In contrast, the molecular weight of biopharmaceuticals can vary by as much as 1 kDa because of the heterogeneity of the production processes and of products originating from the same process. This complexity of protein products is central to the challenges associated with defining their safety and efficacy.

Similarity is a natural extension of comparability, and scientific exercises need to be conducted to demonstrate that a patient is receiving a biological drug that is comparable to the same drug produced before a change in the manufacturing process. Changes to manufacturing process can range from the relatively simple procedure of changing the cellular harvesting method (in which recovery is not affected) to more complex procedures, such as the replacement of a stabilizer or introduction of a new cell line. A comparability exercise is a stepwise approach to development using side-by-side comparisons of the biological product before and after manufacturing changes. This exercise begins with extensive analytical and biological characterization. Animal or human studies are then conducted, if needed, to answer scientific questions still remaining after analytical and biological characterization and comparison. If "no differences" exist between these products, the new product can be substituted for the old. A similar approach is deemed necessary for biosimilars. Key factors that influence the approval process include evidence of integrity and consistency of the manufacturing process; conformance of manufacturing standards to applicable regulations; demonstration of product consistency with appropriate reference standards or comparators (using relevant assays), including comparative PK and pharmacodynamic (PD) data; and the extent of clinical data and experience with the approved product. Immunogenicity assessment has always been a key concern related to approval of follow-on protein products. Although significant advances have been made in predicting immunogenicity using *in silico, in vitro*, and *in vivo* tools, human clinical trials continue to remain the centerpiece of immunogenicity assessment.

The International Nonproprietary Names (INN) program directed through the World Health Organization has the purpose of assigning nonproprietary names to medicinal substances. Assigning INNs to protein therapeutics is often a difficult process because of their complexity. For example, when products have significant differences in glycosylation, such as with the epoetin products, different Greek letters are attached to their INNs. The idea of a biosimilar is based on regulations, but the system for assigning INNs needs to be based on scientific characterization of the biosimilar and comparison with a reference product. The focus of this discussion also is the issue of separate INNs for the reference product and the biosimilar. Justification, for example, for separate INNs has been to ensure adequate postapproval pharmacovigilance and to prevent inappropriate substitution of these products [14]. Regulatory agencies in both the United States and Europe have realized that a pathway for marketing approval of biosimilars requires a different structure and guidelines compared with conventional generics to ensure quality, safety, and efficacy. One of the foundational principles of the European framework is that

biosimilars are expected to be similar, not identical, to the innovator biologics they seek to copy [15].

## 12.7 CURRENT REGULATORY STATUS AND PATHWAYS TO BIOSIMILAR PRODUCTS

### 12.7.1 Europe

***12.7.1.1 Approval Process for Generic Synthetic Small Molecules*** In the European Union, rising health care costs had a profound influence on the growth of the generics industry. Currently, there are several marketing authorization procedures in the EU: a centralized procedure, a mutual recognition procedure (MRP), and a decentralized procedure (along with the individual national registration process). Generic manufacturers of centrally approved reference products have the option of applying through centralized or decentralized procedure. Generic applications normally are submitted through the MRP, which enables national assessment done on part of the market authorization in one reference member state (RMS) to be mutually recognized by other member states, that is, concerned member states (CMS). The legal text of the MRP is provided in Directive 2001/83/EC as amended in by Directive 2004/27/EC, and further guidance is given in the Notice to Applicants, which forms Chapter 2 of the Rules Governing Medicinal Products in the European Union. The Directive 2001/83/EC as amended gives the legislative basis for bioequivalence. Although some similarities to the generic pathway for biosimilars have indeed been built in with respect to small molecules, the one main factor discussed earlier that distinguishes biosimilars from generic drugs is their capacity to elicit an immune response [16].

***12.7.1.2 Approval Process for Biosimilars in Europe*** The regulation of biosimilar drugs was a contentious issue in the EMA. The EMA had been involved in preparing a regulatory framework for biosimilars since 1998 (Concept Paper on the Development of a CHMP Guideline on Comparability of Biotechnology-derived Products [CHMP/BWP/1113/98]). Subsequently, the Committee for Medicinal Products for Human Use (CHMP) issued a Guideline on Similar Biological Medicinal Products (EMEA/CHMP/437/04) [17]. The biological medicinal products in Europe were established with Directive 2001/83/EC, which provided a clear foundation for EMA for future approval process for biosimilars. Specific guidelines were introduced as amendment to Article 10 (Article 10[4] and section 4, Part II, Annex I to the Directive 2001/83/EC known as "Annex 1"). Annex I (Part 2, Paragraph 4) became incorporated as part of the Commission Directive 2003/63/EC, which approved the concepts of biosimilar and gave the EMA mandate to develop its own guidelines on preclinical and clinical data. The EU Directive 2003/63/EC, Annex Part II, Point 4 for "Similar Biological Medicinal Products" states that "the information to be supplied shall not be limited to pharmaceutical, chemical and biological data, supplemented with bioequivalence and bio-availability data." In fact,

the type and amount of additional data (i.e., toxicologic and other nonclinical and appropriate clinical data) shall be determined on a case-by-case basis in accordance with relevant scientific guidelines published by EMA. Directive 2004/27/EC details negotiations between the Council of the European Union and European Parliament on amendments to Directive 2001/83/EC, including the "Bolar Clause," which allowed full development of biosimilars before the originator's patent expired. The European Directive 2004/27/EC addresses the biosimilar medicines subject as follows: when a biological medicinal product that is similar to a reference biological product does not meet the conditions in the definition of generic medicinal products, owing to, in particular, differences relating to raw materials or differences in manufacturing processes of the biological medicinal product and the reference biological medicinal product, the results of appropriate preclinical tests or clinical trials relating to these conditions must be provided. The type and quantity of supplementary data to be provided must comply with the relevant criteria stated in Annex I and the related detailed guidelines. In 2005, the EMA CHMP issued an overarching biosimilars guideline, "Guideline on Similar Biological Medicinal Products," (EMEA/CHMP/437/04) and two guidelines for consultation on the quality issues (EMEA/CPMP/BWP/3207/00 rev 1) and on the nonclinical and clinical issues (CHMP/3079/02 and EMEA/CHMP/BMWP/101695/2006) to be considered for the development of biosimilars.

As stated in Section 4, Part II, Annex I to Directive 2001/83/EC, the EMA may develop additional guidance documents addressing quality and nonclinical and clinical aspects. These include:

- Guideline on Comparability of Medicinal Products Containing Biotechnology-Derived Proteins as Active Substance—Quality Issues (EMEA/CPMP/BWP/49348/05)
- Guideline on Comparability of Medicinal Products Containing Biotechnology-Derived Proteins as Active Substance—Clinical and Non-clinical Issues (EMEA/CHMP/BMWP/42832/05)

The key EMA guidelines are listed in Table 12.8.

Essentially, Directive 2001/83/EC and updates 2003/63/EC and 2004/27/EC lay out a general pathway for approval of biosimilars. According to these directives, comparability studies will be required to establish the similarity between the biosimilar and the reference protein therapeutic (which must already have marketing authorization in the European Union) in terms of quality, safety, and efficacy. According to Article 57 (1)(n) of the Regulation (EC) No. 726/2004, the EMA shall provide acting particularly through its committees and advice on the conduct of the various tests and trials necessary to demonstrate the quality, safety, and efficacy of medicinal products. For most biosimilars, the comparability exercises proceed in a stepwise fashion (Fig. 12.5) [18]. In the first step, a comparison of the quality of the test and the reference protein therapeutic is made. Any differences or concerns in the quality between the test and the reference product will affect the details and amount of comparative nonclinical and

**TABLE 12.8 Current EU Biosimilar Guidances**

| Reference Number | Guideline | Scope | Release Date | Effective Date |
|---|---|---|---|---|
| CPMP/BWP/3207/00 Rev.1 | Guideline on Comparability of Medicinal Products Containing Biotechnology-Derived Proteins as Active Substance—Quality Issues | All biosimilars | December 2003 | December 2003 |

clinical bridging studies that will be required in further steps. Clinical comparability studies usually consist of PK and PD studies in healthy volunteers followed by comparative safety and efficacy trials in patients with the most sensitive and relevant indication. (Specific target study populations are recommended in the EMA guidelines for each of the current categories of biosimilars.)

The EMA CHMP has released for consultation several product-class specific guidelines for the development of several biosimilars, including recombinant human granulocyte; colony-stimulating factor; recombinant human insulin; somatropin; erythropoietin; and, most recently, low-molecular-weight heparins, which have been helpful in several approvals to date (Table 12.9). The product class-specific guidelines stop short of providing precise equivalence margins and do not prescribe a fixed standard for approval. There is still considerable room to maneuver when it comes to negotiating precise standards for approval of any one biosimilar.

Biosimilars that cannot currently be fully characterized because of their complexity (structural, manufacturing) or lack acceptable analytical procedures and technology or clinical and regulatory experience may not be acceptable using the "similar biological medicinal product" approach. In 2010, the EMA released draft versions of two guidelines relating to the regulatory approval of mAbs: the "Guideline on Biological Medicinal Products Containing Monoclonal Antibodies" and the "Guideline on Immunogenicity Assessment of Monoclonal Antibodies Intended for *In Vivo* Clinical Use." Both guidelines were subject to public consultation until May 31, 2011. The former regulation for the approval of

biosimilar mAbs was long awaited by the pharmaceutical industry because many basic patents for therapeutic mAbs will expire within the next couple of years. The present guideline sets forth the nonclinical and clinical requirements for mAb-containing medicinal products claiming to be similar to another one already marketed (i.e., biosimilars) and complements several previous guidelines for biosimilar medicinal products based on which 13 such products have been approved so far in Europe. The guideline is intended to provide product-specific guidance that presents the current view of the EMA on the demonstration of biosimilarity of two mAb-containing medicinal products. Although the new guideline is specifically directed to mAbs, it states that "the principles discussed may also, on a case-by-case basis, be relevant to related substances like, for example, fusion proteins based on IgG Fc. However, second- or next-generation biologicals that are structurally or functionally altered, in comparison with already licensed reference products, to gain an improved or different clinical performance" (i.e., biobetters) are beyond the scope of the guideline.

The second guideline on the immunogenicity assessment of mAb that was released by the EMA is applicable to all biological medicinal products containing mAbs, not just biosimilars. The guideline puts emphasis on the evaluation of clinical consequences of unwanted immune response for each mAb. The mode of mAb action is critical in this assessment because many mAb lyse or induce apoptosis in cells. Also important is whether adverse events such as infusion reactions can be properly handled by neutralizing the mAb with other antibodies or with medication. One standard requirement is that all mAbs will require a validated screening assay followed by a validated neutralizing assay. All antibodies must be classified as neutralizing or non-neutralizing, regardless of their risk level.

The "centralized" procedure has been made mandatory for all products derived from biotechnology. Under the centralized procedure, application for market approval is submitted to the EMA. The EMA issues an opinion (favorable or unfavorable) to the European Commission (EC), which then makes the final approval. Approval by the EC is valid in all EU member states. Any quality data for the biosimilar must fulfill all requirements for Common Technical Document (CTD) Module 3 as defined in Annex I to Directive 2001/83/EC and satisfy the technical requirements of the monographs of the European Pharmacopoeia and any additional requirements, such as defined in relevant CHMP and ICH guidelines.

Note: CTD is an assembly of all the quality, safety, and efficacy information in a common format for regulatory review processes and strives to eliminate the need to reformat the information for submission to the different ICH regulatory authorities.

*Module 3* A full quality dossier (chemical, pharmaceutical, and biologic information) is required for biosimilars. This should be supplemented by the demonstration of comparability (EMEA/CPMP/BWP/3207/00 and EMEA/CHMP/BWP/49348/05).

*Module 4* Before initiating clinical development, nonclinical studies should be conducted. The approach taken to reveal the similarities and differences between the biosimilar and reference product will need to be fully justified. Normally, other routine toxicologic studies, such as safety pharmacology, reproduction toxicology, mutagenicity, and carcinogenicity studies, are not required for biosimilars unless indicated by the results of repeat-dose studies (EMEA/CHMP/BMWP/42832/05).

*Module 5* Even though efficacy can be comparable, the biosimilar can show differences in the safety profile (in terms of severity or adverse events incidence). Clinical studies (rather than the bioequivalence studies used for traditional generics) are needed to support the biosimilar product's safety and effectiveness. In particular, the studies must address immunogenicity.

*Extrapolation of Indication* Under certain circumstances, the EMEA allows extrapolation of indication, that is, a biosimilar that has demonstrated comparable safety and efficacy in the "most sensitive" indication can be assumed to be able to extrapolate that safety and efficacy to other indications of the reference product (EMEA/CHMP/BMWP/42832/05).

The EU pharmaceutical legislation review [19] has resulted in a period of 8 years of data exclusivity for innovator product with an additional 2 years of market exclusivity, which can be extended further by a year (8 + 2 + 1) if a new indication is added within first 8 years for all registration procedures. In terms of patents the European Union now has the highest patent protection level in the world because of various regulatory situations, including patents for biotech products; market protection periods for 20 years; patents extendable to additional 5 years by Supplementary Certificate Regulation (1768/92/EEC); and patents that are also granted for new uses, dosages, and changes in formulations. The Supplementary Protection Certificate (Council Regulation [EEC] 1768/92) is a regulatory initiative introduced to give extended market protection to patented pharmaceutical products to compensate for time lost between patent filing and market authorization.

### 12.7.2 The United States

***12.7.2.1 Approval Process for Generic Synthetic Small Molecules*** Conventional small molecule drugs are regulated under the FDC Act passed in 1938 in the United States. Under this act, new innovator drugs must apply for marketing approval through a New Drug Application (NDA) under Section 505(b)(1). The Drug Price Competition and Patent Term Restoration Act (Hatch-Waxman Act) [20], enacted in 1984, amended the FDC Act and laid out a pathway for approval of generic versions of innovator conventional drugs. The Hatch-Waxman Act provides 5 years of market exclusivity to the sponsor of a new chemical entity (NCE), during which time applications cannot be submitted for alternate versions of the NCE). Furthermore, sponsors can receive 3 more years of market exclusivity for modifications to existing

products that require new clinical investigations. A method of permission to a generic drug sponsor to market its product is provided through FDA approval of an Abbreviated New Drug Application (ANDA) as described in Section 505(j) of the FDCA under the principle that "it is wasteful and unnecessary to carry out studies to demonstrate what is already known about a drug." The generic version of an innovator drug must essentially be identical to the innovator drug in active ingredient, dosage form, strength, route of administration, labeling, quality, performance characteristics, and intended use. Another ANDA route for generic drug approval also added to the FDC Act by the Hatch-Waxman Act, Section 505(b)(2) can be used by drugs that have been modified compared with the previously approved innovator drug yet are comparable. Such an application contains full reports of safety and investigation, but some of the investigations "were not conducted by or for the applicant and for which the applicant has not obtained a right of reference or use from the person by or for whom the investigations were conducted" (21 U.S.C. 355(b)(2). Drugs using this approach can include new chemical or molecular entities and drugs that have been changed compared with the previously approved version. According to the Office of Generic Drugs (OGD), which is part of the US FDA's Center for Drug Evaluation and Research (CDER), "a generic drug is identical, or bioequivalent to a brand name drug in dosage form, safety, strength, route of administration, quality, performance characteristics and intended use." Bioequivalence is defined in the United States in the Code of Federal Regulations, Title 21, Part 320.1 [21].

***12.7.2.2 Approval Process for Biosimilars*** An approval scheme, analogous to an ANDA under the Hatch-Waxman Act, cannot be applied to biosimilars because of the inability to declare the follow-on version identical to the innovator product and described differences to conventional small molecule drugs. As explained by Janet Woodcock of the FDA in testimony to the US House of Representatives on March 26, 2007, because of "the variability and complexity of protein molecules, current limitations of analytical methods, and the difficulties in manufacturing a consistent product, it is unlikely that, for most proteins, a manufacturer of a follow-on protein product could demonstrate that its product is identical to an already approved product. Therefore, the Section 505(j) generic drug approval pathway will not ordinarily be available for protein products" [22].

Starting with the Biologics Control Act, Congress has regulated most biologics separately from small molecules. In 1944, the Biologics Control Act was incorporated into the PHSA, under which biologics are still regulated today (for historical reasons, certain biologics are regulated under the FDCA, including hGH, calcitonin, and hyaluronidase) (Table 12.10). Historically, some simpler protein therapeutics have been approved under the FDC Act, including insulin, hyaluronidase, menotropins, and hGHs (Table 12.11). When recombinant proteins and monoclonal antibodies began development in the 1970s and 1980s, these were regulated as follows:

1. By the CDER under the Food, Drug and Cosmetic Act (FDCA) as drugs when they were hormones such as insulin, hGH, and PTH derivatives

**TABLE 12.10 Food and Drug Administration Center Regulatory Responsibility for Therapeutic Biological Products**

| CDER | CBER |
|---|---|
| mAbs (*in vivo* use) | Cellular product, including products composed of human, bacterial, or animal cells |
| Proteins intended for therapeutic use: cytokines (e.g., interferons), enzymes (e. g., thrombolytics) | Vaccines |
| Immunomodulators (nonvaccine, nonallergenic) | Allergenic extracts |
| Growth factors, cytokines, hormones, mAbs intended to mobilize, stimulate, decrease, or alter production of hematopoietic cells *in vivo* | Antitoxins, antivenoms, venoms |
| — | Blood, blood components, plasma-derived products, recombinant and transgenic versions of plasma derivatives |

CBER: Center for Biologics Evaluation and Research; CDER: Center for Drug Evaluation and Research; mAb: monoclonal antibody.

**TABLE 12.11 Examples of a Few Therapeutic Peptide and Protein Molecules Currently Marketed in the United States**

| | |
|---|---|
| Peptides | Antibiotics: bacitracin, bleomycin<br>Hormones: corticotrophin, glucagon, oxytocin, vasopressin<br>Others: polymixin B, cyclosporine etc |
| Nonglycosylated proteins | Interleukins: andresleukin (IL-1), denileukin diftitox (fusion, protein-IL2 + DT), anakinra (IL2)<br>Interferons: interferon-α-n1, interferon-α2a, interferon-α2b<br>Enzymes and inhibitors: lactase, trypsin, chymotrypsin, urokinase, papain<br>Growth factors and hormones: filigrastim, somatropin, menotropins<br>Others: insulin, hemoglobin |
| Glycosylated proteins | Interferon-β1a, alteplase, erythropoietin, normal immune globulin, factor VII, factor IX, etanercept, sargromostin |
| Monoclonal antibodies | Avciximab, palivizumab, basiliximab, gentuzumab, satumomab |

2. By the Center for Biologics Evaluation and Research (CBER) under the PHSA as biologics when they were cytokines or blood factors such as factor VIII for hemophilia
3. As other recombinant proteins and mAbs came under development, the CBER held primary responsibility for this review, with the CDER retaining responsibility for hormones such as insulin and hGH.

In 2003, all therapeutic proteins were transferred from the CBER to the CDER. This reassignment of review responsibility did not impact the legal classification of these protein products, such that the CDER assumed responsibility for the review and approval of biologics approved under Section 351 of the PHSA.

Table 12.11 shows categories of a few therapeutic peptide and protein molecules currently marketed in United States. To date, at least six biosimilars have been approved in the United States by the FDA, perhaps the most prominent of which is the follow-on of somatropin. Sandoz's Omnitrope intended to replicate the recombinant hGH somatropin (Genotropin, Pfizer), which is regulated under the FDCA. Because hGH products are approved under the FDCA, the abbreviated approval of Omnitrope did not establish a pathway for follow-on versions of biopharmaceuticals regulated under the PHSA. Several other biosimilars approved in the United States under Section 505(b)(2) include Hylenex (hyaluronidase), Hydase (hyaluronidase), Amphadase (hyaluronidase), Fortical (calcitonin), and GlucaGen (glucagon). Despite approval of these biosimilars by the FDA, these products have not been declared as directly substitutable for the reference products. The appropriateness of a Section 505(b)(2) application and the information required for each of the biosimilar approvals have been decided on a case-by-case basis by the FDA. Some of the factors that have influenced the amount and type of data required by the FDA for marketing approval of biosimilar include:

- The robustness of the manufacturing process
- The degree to which structural similarity can be assessed; minor differences in clinically inactive components are permitted.
- The extent to which mechanism of action was understood
- The existence of valid, mechanistically related PD assays
- The comparative PK
- The comparative immunogenicity
- The amount of clinical data available and extent of experience with the original product, or products

Because no defined regulatory pathway for the FDA to review or approve biosimilars in the United States was available, several bills to set up such a pathway were introduced in Congress. The challenge was to approve necessary regulations that protect innovator companies while maintaining the safety and efficacy of biosimilar products that would increase competition and lower drug costs. Five bills were introduced in the 110th Congress (January 3, 2007–January 3, 2009); however, none received a vote. Subsequently, two unique bills were introduced in the 111th Congress (January 3, 2009–January 3, 2011) related to biosimilars, including a reintroduction of The Access to Life Saving Medicine Act, now titled The Promoting Innovation and Access to Life Saving Medicine Act by Representative Waxman and Senator Schumer, and a reintroduction of The Pathway for Biosimilars Act by

Representative Eshoo (Table 12.12). The two bills survived committee votes in US Congress and the Senate, respectively, before being reconciled and passed by the House of Representatives in March 2010.

On March 23, 2010, President Obama signed into law the reconciliation bill that finalized Congress's health care reform legislation, the Patient Protection and Affordable Care Act (Affordable Care Act) (Pub. L. 111–148) [23]. The Affordable Care Act contains a subtitle called the Biologics Price Competition and Innovation Act of 2009 (BPCI Act) that by inserting subsection (k) amends the PHSA and other statutes to create an abbreviated approval pathway for biological products (chemically synthesized polypeptides are excluded) shown to be biosimilar to or interchangeable with an FDA-licensed reference biological product (Sections 7001–7003 of the BPCI Act). Included in this law is a provision to balance consumer interests and innovation for biological products through the Biologics Price Competition and Innovation Act.

The definition of "biological product" under the BPCI Act has been redefined to include:

(b)(2) The term "biosimilar" or "biosimilarity" in reference to a biological product that is the subject of an application under subsection (k), means

(A) that the biological product is highly similar to the reference product notwithstanding minor differences in clinically inactive components; and

(B) there are no clinically meaningful differences between the biological product and the reference product in terms of the safety, purity, and potency of the product.

(3) The term 'interchangeable' or 'interchangeability', in reference to a biological product that is shown to meet the standards described in subsection (k)(4), means that the biological product may be substituted for the reference product without the intervention of the health care provider who prescribed the reference product.

(4) The term "reference product" means the single biological product licensed under subsection (a) against which a biological product is evaluated in an application submitted under subsection (k).

The objectives of the BPCI Act are conceptually similar to those of the Drug Price Competition and Patent Term Restoration Act of 1984 (Pub. L. 98–417). Biosimilars are required to have the same route of administration, dosage form, and strength as the reference product and use the same mechanisms of action (MOAs) for the conditions of use but only to the extent that the mechanism of action is known. A biological product may be demonstrated to be "biosimilar" to a biological reference product based on data derived from analytical studies, animal studies, and a clinical study or studies if the product is shown to be highly similar to the reference product, notwithstanding minor differences in clinically inactive components, and if there are no clinically meaningful differences between the biological product and the reference product in terms of safety, purity, and potency.

**TABLE 12.12 Comparison of H.R. 1427, The Access to Life Saving Medicine Act (Now Titled The Promoting Innovation and Access to Life Saving Medicine Act), and H.R. 1548, a Reintroduction of The Pathway for Biosimilars Act**

| Provision | Waxman Bill (H.R. 1427) | Eshoo Bill (H.R. 1548) | Hatch-Waxman Act (1984) |
|---|---|---|---|

*Measured from date of first approval of new product using a given biologic.
†Measured from date of first approval of new indication.
‡Added to the end of exclusivity period provided for new product or indication.
ANDA: Abbreviated New Drug Application; FDA: Food and Drug Administration.

The BPCI Act also includes, among other provisions, a 12-year period of marketing exclusivity from the date of first licensure of the reference product, during which approval of a 351(k) application referencing that product cannot be made effective; an exclusivity period for the first biological product submitted in a 351(k) application that has been determined to be interchangeable with the reference product for any condition of use, during which a second or subsequent biological product may not be determined interchangeable to that reference product; and a transition provision for protein products that have been or will be approved under section 505 of the FD&C Act (21 U.S.C. 355) prior to March 23, 2020.

***12.7.2.3 Impact on Patent Prosecution, the Food and Drug Administration, and Litigation Practices (Fig. 12.6) [24]*** Several provisions of the BPCI Act will impact patent prosecution and litigation, as well as FDA practice. Areas of particular interest and opportunity are listed below:

*Pioneer Exclusivity* The BPCI Act grants pioneers 12 years of marketing exclusivity from application approval (with a potential further 6 months for pediatric studies). In addition, during the first 4 years of such exclusivity (or 4 years plus 6 months for pediatric studies), the follow on biologics (FOB) applicant cannot submit an FOB application.

*Biosimilar Applicant Exclusivity* Biosimilar applicants are awarded exclusivity for being the first product determined to be "interchangeable" with the pioneer biologic. The law contains provisions for marketing exclusivity for both the interchangeable biological product and the reference product. For biological products labeled biosimilar, no marketing exclusivity is available. The first product to be granted interchangeability against a specific reference standard receives 12 months of marketing exclusivity. If changes are made to a reference product, 12 years of exclusivity may be granted if a new Biologic License Application (BLA) must be filed. Two conditions are described in the legislation to be granted this exclusivity:

1. A structural change made to the molecule that results in a change in safety, purity, or potency
2. No change to the molecular structure; the indication, route of administration, dosing schedule, dosage form, delivery system, delivery device, or strength must also remain the same

Marketing exclusivity is extended for the conduct of pediatric studies and orphan drugs.

The marketing periods described above are extended by 6 months for new biosimilar or interchangeable biological products or already marketed biological products if studies are completed in the pediatric population and the reports are acceptable to the agency. This period may not be extended if the determination is made later than 9 months before the expiration period. For drugs for rare diseases, exclusivity is extended an additional 6 months to 7 years, 6 months.

**FIGURE 12.6** Patent infringement resolution and negotiations: process and timelines. BLA: Biologic License Application.

*Patent Notices and Pre-litigation Disclosures (see Fig. 12.6)* Unlike in the Hatch-Waxman context, in which pioneers provide notice of the patents that protect their product in a public forum (the *Orange Book*), the BPCI Act provides for private notices of such patents.

*Notice to Pioneer of Product and Process* The biosimilar applicant must provide a copy of its application and a description of its manufacturing process to the pioneer within 20 days of acceptance of the application for review. This information and data must be used for the sole and exclusive purpose of determining whether a claim of patent infringement could be reasonably asserted. Written consent from the applicant is required to disclose this confidential information to "any other person or entity," and

this consent cannot be reasonably withheld. Because of the irreparable harm experienced by the applicant if this confidential information is disclosed to others, the court may consider injunctive relief for violations.

- Pioneers' list of relevant patents: Within 60 days of the production of the application and manufacturing process, the pioneer must identify the relevant patents it could assert, the patents to which it has an exclusive license, and the patents it is willing to license. After receipt of this confidential information, a formal resolution process takes place that involves the mutual exchange of information relating to patents. Timing constraints have been put in place to ensure that the process moves forward as expeditiously as possible. Within 60 days of the reference product sponsor's receipt of the subsection (k) BLA and manufacturing processes data and information, the sponsor is to provide the applicant with a list of patents for which a claim of infringement could be reasonably asserted. In addition, the reference product sponsor needs to identify patents on the list that it would be willing to license to the applicant. Within 60 days of receiving this list, the subsection (k) applicant must provide a detailed statement of the reason why the claims listed by the reference product sponsor are invalid, unenforceable, or will not be infringed upon and a response to the licensing offer or a statement that marketing of the biosimilar or interchangeable biological product will not begin before the patent expires. The applicant may provide to the reference product sponsor a list of patents for which a claim of infringement could reasonably be asserted. Within 60 days of receipt of this response, the reference product sponsor must provide to the applicant a detailed statement of why the listed patents are infringed and a response to the validity and enforceability statements.
- Biosimilar applicant's contentions: Within 60 days of the production of the list of patents by the pioneer, the biosimilar applicant shall provide a detailed (i.e., claim-by-claim) statement that describes the factual and legal basis for why each patent listed by the pioneer is not valid and enforceable or would not be infringed by commercial manufacture of the biosimilar product or state that the FOB applicant does not intend to commercially market any biosimilar product until the date one or more patents expire.

*Determining Which Patents Will Be Litigated* The BPCI Act also provides that the parties shall engage in good faith negotiations with a goal of agreeing on which, if any, patents should be litigated. The parties are given 15 days to resolve any differences.

*Limits on Staying Biosimilar Approval* The BPCI Act does not grant pioneers an automatic stay to prevent generic approval during the pendency of patent litigation. Because the disclosure periods in the BPCI Act are very short and far more analysis is demanded up front than in the Hatch-Waxman setting, this is the time for pioneers to audit their portfolios of patents relating to biologic patents to identify and fix any potential issues. They should stress test the patents for the validity and

non-infringement positions biosimilar applicants are likely to take hence pioneers need to plan and refine their portfolios accordingly.

On November 2, 2010 there was a public hearing because the FDA was seeking comments on several issues (partial list below) [25]:

1. What scientific and technical factors should the agency consider in determining whether the biological product is highly similar to the reference product notwithstanding minor differences in clinically inactive components?
2. What range of structural differences between a proposed biosimilar product and the reference product is consistent with the standard "highly similar" and may be acceptable in a 351(k) application if the applicant can demonstrate the absence of any clinically meaningful differences between the proposed biosimilar product and the reference product?
3. Under what circumstances should the agency consider finding that animal studies or a clinical study or studies are "unnecessary" for submission of a 351(k) application?
4. What factors should the agency consider in evaluating the potential risk related to alternating or switching between use of the proposed interchangeable biological product and the reference product or among interchangeable biological products?
5. What types of guidance documents for industry should be a priority for the agency during the early period of implementation?

Subsequently, on February 9, 2012 the FDA issued the following three draft guidance documents on biosimilar product development to assist industry in developing such products in the United States. Comments to the draft guidances were due by April 16, 2012 followed by a public meeting on May 11, 2012.

- "Scientific Considerations in Demonstrating Biosimilarity to a Reference Product": This draft guidance is intended to assist companies in demonstrating that a proposed therapeutic protein product is biosimilar to a reference product for the purpose of submitting an application, called a "351(k)" application, to the FDA. This draft guidance describes a risk-based "totality-of-the-evidence" approach that the FDA intends to use to evaluate the data and information submitted in support of a determination of biosimilarity of the proposed product to the reference product. As outlined in the draft guidance, the FDA recommends a stepwise approach in the development of biosimilar products.
- "Quality Considerations in Demonstrating Biosimilarity to a Reference Protein Product": The draft guidance provides an overview of analytical factors to consider when assessing biosimilarity between a proposed therapeutic protein product and a reference product for the purpose of submitting a 351(k) application. This includes the importance of extensive analytical, physicochemical, and biological characterization in demonstrating that the proposed

biosimilar product is highly similar to the reference product notwithstanding minor differences in clinically inactive components.

- "Biosimilars: Questions and Answers Regarding Implementation of the Biologics Price Competition and Innovation Act of 2009": The draft guidance provides answers to common questions from people interested in developing biosimilar products. The question-and-answer format addresses questions that may arise in the early stages of product development, such as how to request meetings with the FDA, addressing differences in formulation from the reference product, how to request exclusivity, and other topics.

Following summarizes a few aspects of the draft guidances:

1. *Stepwise approach and totality of evidence to demonstrate and assess biosimilarity:* The concept of a totality-of-the-evidence approach can serve as an appropriate and efficient approach to demonstrating biosimilarity. The more comprehensive and robust the comparative structural and functional characterization, the more useful such characterization can be in determining what additional studies may be needed. So if a more rigorous structural and functional comparison shows minimal or no difference between the proposed product and reference product, the stronger the scientific justification for a selective and targeted approach to animal or clinical testing to support a demonstration of biosimilarity. Such assessments should used state-of-the-art methods, consistent test material and reference product, consistent reagents, and sensitive assays. Safety and immunogenicity need to be evaluated in appropriate preapproval clinical studies and, when appropriate, postmarketing studies of sufficient duration should be done to detect and assess differences in a sensitive population. Also, the draft guidances imply that in some circumstances, the amino acid sequence of a biosimilar and its reference product may be different. The FDA may need to clarify the extent to which sequence variants can exist within the concept of biosimilarity. Also, the guidance suggests FDA expects injectable biologicals to have both the same total content of drug substance (in mass or units of activity in a container closure) and the same concentration of drug substance (in mass or units of activity per unit volume) as the reference product to have same strength. The FDA also expects that applicants characterize, identify, and quantify impurities (product and process related as defined in ICH Q6B) in the proposed biosimilar product and the reference product. Some innovator companies, however, have argued that biosimilar development program should include, at a minimum, side-by-side analytical evaluations as well as comparative nonclinical studies (*in vitro, in vivo*, or both), comparative human PK and PD studies (when a relevant response marker exists), and a comparative clinical study addressing safety and efficacy separately or jointly.
2. *Interchangeability:* The initial guidances do not reflect in detail on interchangeability. Hence, the sponsor may need to seek biosimilar designation first followed by additional data to request designation of interchangeability later. The

**FIGURE 12.7** A model of developing "goal posts."

opportunity to seek interchangeability at the time of initial application appears to be vague. This raises concerns whether interchangeability is a higher standard of approval than biosimilarity and thus presents a complex set of regulatory challenges to be addressed fully in a separate guidance. McCamish and Woollett [18] have explained a model of developing "goal posts" whereby a scientific basis for establishing a highly similar biosimilar is initiated (Figure 12.7) [18]. They suggest that even originator biologic products undergo changes over time (e.g., when manufacturing process is modified by scaling up or transferred to alternate sites). Changes in originator product attributes provide a distribution of attributes that should be considered acceptable because the products were subsequently administered to patients successfully. The limits to distribution of such attributes are what they call "goal posts," which could be used to demonstrate acceptability of a biosimilar. After "goal posts" are established for an originator reference product, an iterative process can be used in developing a biosimilar in which the product is fully evaluated by physicochemical and biological characterization compared with the originator product. If product attributes fall outside established "goal posts," various process steps can be modified to produce product attributes that are within the variability of the originator product. This process can be repeated until highly similar product attributes are achieved. The degree of similarity that is established can be based on analytical characterization that is run in parallel with iterative process development activities. Depending on the extent that product attributes of the biosimilar overlap with those of the originator product, preclinical and clinical development can be abbreviated compared with developing a novel biologic.

The goal posts of biosimilarity are established by the biosimilar sponsor by their analysis of the distribution of product attributes present in the reference product pre- and postmanufacturing change. They then use these to select the design space for their biosimilar candidate. Although the complete quality range may be quite broad for the life of the reference product, the biosimilar sponsor will select a tighter range of control for its biosimilar product.

In May 2006, Sandoz achieved an approval for Omnitrope (somatropin) based on a demonstration of "high similarity" or comparability to Pfizer's Genotropin (somatropin), and in July 2010, the approval of enoxaparin as a fully

substitutable generic to Sanofi-Aventis' Lovenox (enoxaparin). In reviewing the enoxaparin file, the FDA established five criteria to determine "sameness" of Sandoz's enoxaparin to Lovenox. These were physiochemical properties, source material, the sugar building blocks, biologic assays, and *in vitro* PD profile. Each of these criteria had to be comparable for the FDA to rule that the two products were the "same." In this case, the analytical characterization, along with other information, provided sufficient data for the FDA to approve the product. Again, enoxaparin was not approved as a biosimilar under the new BPCI Act pathway, but the scientific approach used by the FDA is equally applicable.

3. *Foreign reference product issues:* The draft "Scientific Considerations Guidance" states that "[t]o obtain licensure of a proposed product under section 351(k) of the Public Health Service (PHS) Act, a sponsor must demonstrate that the proposed product is biosimilar to a single reference product that previously has been licensed by FDA. However, under certain circumstances, a sponsor may seek to use data derived from animal or clinical studies comparing a proposed product with a non-U.S.-licensed product to address, in part, the requirements under section 351(k)(2)(A) of the PHS Act."

   The challenge here is foreign versions of US-licensed reference products can significantly vary in the extent to which they are similar to the US product. In some cases, a single manufacturer may release the same drug product (with differences only in packaging and labeling) from the same manufacturing plant(s) into both the US and non-US markets. In other cases, products intended for different markets may be manufactured independently or comply with locally specific quality or pharmacopeial standards. When products are manufactured by more than one entity, two products that were once related may have diverged from each other over time in subtle but important ways. Moreover, some innovative products manufactured abroad may have even more fundamental differences from the products intended for marketing in the United States (e.g., because of the use of different cell lines, formulations, container closure, or shipping methods. The foreign comparator product may not have the same formulation as the US-licensed reference product. The manufacturing facilities for the foreign comparator product may not be in compliance with current good manufacturing practices (cGMPs) and may not be subject to regularly scheduled inspections by the FDA or equivalent regulatory agency. When a foreign comparator product can be determined to be fully representative of the US-licensed reference product, a sponsor is allowed to use data derived from a study conducted with this foreign comparator to address components of the statutory requirements. This helps avoid unethical conduct of duplicative trials. Because a scientific stepwise approach for bridging US-licensed product to non–US-licensed biologic is the basis of allowing use of foreign sourced biologic as a comparator agent in any characterization, animal, or clinical efficacy and safety trials that are needed. As suggested by McCamish and Woollett [18], structural and functional data can be the foundation for bridging of the US reference product to the foreign comparator biologic (Fig. 12.8). If residual

**FIGURE 12.8** Iterations toward biosimilar development. PD: pharmacodynamics; PK: pharmacokinetics.

uncertainty remains with regards to comparability of the biologic, PK and PD data could be used.

Because of changes an innovative product sponsor may make to its manufacturing process, a reference product studied in a biosimilar development program may change (either during or after product development) in subtle ways that are unknown to the biosimilar applicant. To address this concern, the FDA could recommend that a biosimilar applicant conduct its analytical, nonclinical, and clinical comparisons during a limited period of time and then establish an internal reference standard. Neither the biosimilar nor the reference product would thus be constrained from improving their processes and complying with cGMP after approval of a biosimilar product. The biosimilar and reference products could be treated as independent products, each standing on their own merits for future manufacturing changes and quality evaluations. To do otherwise could constrain manufacturing improvements.

4. *Animal data:* Nonclinical *in vivo* safety evaluation of a biosimilar is generally required to be conducted before clinical studies. The PHSA states that an application must include information demonstrating that the biologic is biosimilar to a reference product based on data derived from animal studies (including the assessment of toxicity), suggesting that the toxicology study

should be designed to compare the two products (not reestablish the toxicity profile of the reference product). The FDA could provide greater clarity with regard to when animal toxicity studies will be appropriate to help inform biosimilar development program planning, and this issue could be further addressed in class-specific guidances.

5. *Clinical studies and immunogenicity assessment:* The draft guidance suggests that an applicant should use a population PK modeling approach to explore potential variability in PK. The draft also suggests that establishing a similar human PK and PD profile may provide a basis for a selective and targeted approach to subsequent clinical testing. However, the FDA has been given the authority to waive any unnecessary analytical and preclinical studies. This is because if only clinical data were to be meaningful, then all requirements to demonstrate analytical similarity and conduct animal study would produce data of little value in determination of biosimilarity or interchangeable biosimilarity. Hence, the scope and magnitude of clinical studies depend on the extent of residual uncertainty about the biosimilarity of the two products after conducting structural and functional characterization and possible animal studies. The guidance also suggests that scope of the clinical program for the purpose of determining clinically meaningful differences may be narrowed to the conduct of the PK and PD studies when appropriate PD markers are available.

   The draft guidance states that if immune response to the reference product is rare, two studies may be needed to evaluate immunogenicity: (1) a premarket study to detect major differences in responses and (2) a postmarket study to detect subtle differences.

6. *Clinical safety and effectiveness data:* The guidance states that comparative clinical safety and effectiveness data are necessary if there are "residual uncertainties" about biosimilarity based on structural and functional characterization, animal testing, human PK and PD data, and a clinical immunogenicity assessment. When the similarity exercise leaves considerable residual uncertainty about the structural and functional similarity of the biosimilar and the reference product, a more rigorous (equivalence) assessment with more traditional endpoints may be necessary.

7. *Clinical trial design:* For biosimilars, when clinical trials are determined to be a useful confirmation of biosimilarity, sponsors may have the option of a variety of study designs. The study design could vary considerably depending on the product, the patient population, and the indication being considered for the initial study (recognizing that not all indications for all biosimilars will need to be studied in human trials). For example, in the approval of Sandoz's granulocyte colony-stimulating factor (GCSF) as a biosimilar in Europe, the clinical trial designs relied primarily on phase 1 studies to show that comparability can be well established using PK and PD studies. Specifically, Sandoz [18] refers to a recent peer-reviewed publication in which they describe the approach to biosimilarity used to develop commercial GCSF, or filgrastims, in some detail. Filgrastim, being a nonglycosylated peptide, is

**FIGURE 12.9** Biosimilar filgrastim compared with the reference product (Neupogen) using three state-of-the-art analytical techniques. (a) Peptide mapping (Zarzio vs. Neupogen). (b) UV CD spectroscopy (higher order structure). (c) Bioactivity—surface plasmon resonance spectroscopy. CD: circular dichroism; UV: ultraviolet.

one of the easiest biologics to re-create, but that clinical studies can be minimal is critically important to consider as the United States implements the abbreviated pathway here. The first step in the process was to demonstrate chemical and biological comparability to the originator. In Figure 12.9, Sandoz scientists [26] documented overlapping peptide mapping, higher order structures comparing multiple batches of the biosimilar with the originator product.

8. *Extrapolation between conditions of use (indications):* According to the draft guidance, a sponsor of a proposed product may seek licensure only for a condition of use that has been previously licensed for the referenced product. In addition, a biosimilar applicant should scientifically justify the extrapolation of clinical data to support a determination of biosimilarity for each condition of use of the reference product for which licensure is sought. Such scientific justification would need to address the MOA(s) in each condition of use for which licensure is sought. The FDA recommends that the sponsor consider whether tested condition of use is the most sensitive one in detecting clinically meaningful differences in safety and effectiveness.

   For a biosimilar sponsor, however, extrapolation is one of the leading reasons why a sponsor may choose to apply to the FDA for a product licensure, hence the guidance's preclude any real opportunity for an abbreviated approach toward a biosimilar approval. Also, it is unconceivable that a biosimilar shown to be

"highly similar" to its reference product not share the same MOA; hence, receptor binding between biosimilar and originator in head-to-head studies should suffice without further elaboration of downstream intracellular signaling. An FDA guidance during early development regarding which populations should be studied to allow extrapolating to all remaining indications would be invaluable.

9. *Pediatric studies and waivers:* The FDA states that a noninterchangeable biosimilar biologic product should be considered to have a new active ingredient. This leads to consequence of pediatric studies being expected for the approval of a biosimilar but not for an interchangeable biosimilar unless the FDA issues a pediatric waiver. The FDA has made it clear in the public statement and guidances encouraging sponsors not to apply for interchangeable biosimilars at this time but to consider a two-step process whereby they achieve a biosimilar approval and then consider a supplement to gain the interchangeable designation. Given that studies with biosimilars will be necessary as a scientific matter if biosimilarity has been established in adults, performing scientifically meaningless studies is unethical. It is therefore important that the FDA make clear the possibility of a waiver for these studies rather than suggest that clinical studies in pediatric populations will be the norm.
10. *Postmarketing safety and assessment:* Postmarketing safety monitoring applies equally to small and large molecules and to originator, biosimilar, and generic drugs irrespective of the sponsors. Postmarketing surveillance is fundamental to defining the safety profile and effectiveness of any product in the marketed setting because clinical development programs are necessarily finite in size and duration and will not always identify rare and unexpected adverse effects. However, it is also inherent in the approval of a biosimilar that the connection has been built as a scientific, regulatory, and legal matter to the prior finding of safety, purity, and potency of the originator product. Hence, the unknown at the time of biosimilar approval is vastly smaller than at the time of the originator product. It is possible for antidrug antibody response to be induced after long-term exposure to a foreign protein. However, it should not be assumed a priori that such events will occur because the biologic is a biosimilar. Nonetheless, if large-scale immunogenicity studies are considered necessary to assess this possibility, they could be conducted after licensure but would also be needed for the requirements for the originator, which may use comparability protocols during transfer or process improvement endeavors.
11. *User fees:* The Federal Food, Drug, and Cosmetic Act, as amended by the Biosimilar User Fee Act of 2012, authorized the FDA to assess and collect fees for biosimilar biological products from October 2012 through September 2017 (Table 12.13). The FDA dedicates these fees to expediting the review process for biosimilar biological products.

**TABLE 12.13 Fee Schedule (2013)**

| Fee Category | Fee Rate for Fiscal Year 2013 |
|---|---|
| Initial BPD | $195,880 |
| Annual BPD | $195,880 |
| Reactivation | $391,760 |
| Biosimilar Biological Product Application | |
| Requiring clinical data | $1,958,800 |
| Not requiring clinical data | $979,400 |
| Biosimilar biological product supplement requiring clinical data | $979,400 |
| Biosimilar biological product establishment | $526,500 |
| Biosimilar biological product | $98,380 |

BPD: biological process development.

## 12.8 CONCLUSION

In the past two decades, the biotechnology industry has made great advances in improving our understanding of manufacturing processes and their starting materials, as well as of the impact they have on product quality. Whereas early biopharmaceutical regulation was grounded by technical limitations, modern biopharmaceutical regulation is driven by tremendous advances in scientific knowledge. Development of analytical tools and techniques has dramatically increased the ability to characterize proteins and substantiate the structure, composition, and function of the therapeutic molecule. These advances enable the detection of small differences in molecular weight; elucidation of primary, secondary, and tertiary protein structures; detection and quantification of posttranslational modifications (i.e., patterns of glycosylation); and improved understanding of structure–function relationships and potential immunogenic responses. Simultaneously, developments in the fields of pharmaceutical and biotechnological manufacturing have greatly improved process efficiency and control.

Sandoz, the generics arm of Novartis, which has three approved biosimilar products, has begun a phase II clinical trial for a biosimilar version of rituximab, the active ingredient in Rituxan/MabThera, an mAb used to treat non-Hodgkin's lymphoma and rheumatoid arthritis, which is marketed by Roche/Genentech and Biogen Idec. The phase II study is targeted to patients with rheumatoid arthritis and aims to demonstrate bioequivalence to the reference product by assessing data on PK and PD as well as efficacy and safety. Sandoz also reported that it has developed a high-yield and large-scale process for rituximab at its facilities in Schaftenau, Austria.

In Japan, Sandoz has gained marketing approval of Japan's first therapeutic biosimilar, Somatropin BD. Also, in Canada, Sandoz has received market authorization for Omnitrope, which is the first biosimilar to achieve approval from Health Canada under Information and Submission Requirements for Subsequent Entry Biologics. An Indian company, Dr. Reddy's Laboratories, has already developed and

received marketing approval for a biosimilar version of the monoclonal antibody rituximab (Genentech, Inc. and Biogen Idec, Inc.), called Reditux.

In summary, the European Union has a well-established and well-documented legal and regulatory pathway for the review and approval of biosimilars. With a biosimilar registration pathway in place in the United States, it is expected to pave the way for the market entry of biosimilars in 2013. The FDA may commit to publishing class-specific guidances that discuss the approval standards and other key implementation issues for particular product classes. Class-specific guidance will provide the most meaningful guidance for manufacturers and will foster the confidence in biosimilars needed for physician and patient acceptance of this new class of product.

Other organizations and countries around the world, including Australia, Canada, Japan, and Switzerland, are also following the same scientific principles for an abbreviated approval pathway for biosimilars. Many Southeast Asian countries, including China, India, and South Korea, also have regulations in place to deal with biosimilars.

# Vaccine Development: History, Current Status, and Future Trends

LEO VAN DER POL and JEAN-PIERRE AMORIJ

## 13.1 INTRODUCTION

Vaccines consist of a heterogeneous group of biopharmaceuticals that show little synergy to allow a standardized approach for product and process development. For a more homogeneous group of recombinant protein biopharmaceuticals, such as monoclonal antibodies (mAbs), a modular approach has been accomplished that reduces the risk and required time for a new development project. These protein products are well-characterized, facilitating a quality by design (QbD) approach. For vaccines, a prospective design approach is complicated by the limited knowledge on host–pathogen interaction, in particular the responses of the human immune system, and the great variability of many pathogens. This frustrates the formulation of product quality features of a vaccine to guarantee the exertion of the desired (protecting) effect. The classical trial-and-error approach for vaccine development is often insufficient to combat variable and immune-deceiving pathogens and generates limited scientific understanding for the present-day desired level of control on process and product. Therefore, it seems promising that progress in scientific understanding of, in particular, the innate immune system enables tailored vaccine design. Knowledge-based adjuvant design and the upcoming recombinant subunit vaccines, conjugate vaccines and virus-like particle (VLP) vaccines, are expected to facilitate a vaccine design based on a structure–function relationship in the future. This chapter presents an overview of vaccine development with special attention on process development and the route toward QbD for vaccines.

Vaccines are a group of biopharmaceuticals [1] that show heterogeneity as broad as the whole group of biopharmaceuticals. This is because pathogens are diverse, and the human immune response to these invaders is complex. For most viral and

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

bacterial intruders, such as tetanus and diphtheria, the immune response elicited by the classical vaccines was sufficient to reach a high level of protection in the developed countries in a very cost-effective manner. However, for the (highly variable) pathogens with immune-deceiving mechanisms, assistance by antiviral agents or antibiotics is required. The enormous impact of the classical vaccines in reducing the disease burden of diseases such as diphtheria, tetanus, whooping cough (pertussis), and polio (DTP-P) is fading from the common active knowledge, but incidents receive considerable attention in the Internet era, creating a great focus on product safety.

The introduction of many recombinant protein products, such as insulin, erythropoietin (EPO), and mAbs, has changed both production techniques and regulatory requirements. For vaccine development and the market, this had great impact, including on trying to meet increasing regulatory demands, including good manufacturing process (GMP) guidelines and substantial clinical trials, because a traditional low-cost product created a serious threshold for the introduction of new vaccines and a great reduction in the number of introduction of new vaccines on the market as well as the number of vaccine manufacturers.

Vaccine development projects that were started after the introduction of the classical vaccines had to face increasing demands in regulatory guidelines such as GMP [2], comparability [3] (product + impurity profile), International Conference on Harmonization (ICH) Q8 [4] (pharmaceutical development, QbD), ICH Q9 [5] (risk assessment), the process analytical technology (PAT) initiative [6], and toward continued process and product improvement using QbD approaches [7,8]. A common theme is gaining sufficient scientific understanding of the product and the process to be able to explain the specific product quality features and explain the rationale behind performing the different process steps under given conditions.

For small molecules and recombinant protein pharmaceutical products, the requirements have been implemented in the development approach and have had a beneficial effect on development time and production performance by providing better control and troubleshooting capabilities. This has resulted in several modular and standard approaches for these biopharmaceutical products. Although the classical vaccines were among the first biotech pharmaceutical products to be introduced in the past century, there exist little modular or standardized development approaches for vaccines. For vaccines, the implementation of the continuously evolving regulatory guidelines is an immense challenge. This is mainly because of the lack of knowledge on host–pathogen interaction (the interaction between the pathogen and the human immune system resulting in an immune response with the required phenotype (markers or correlates of protection [CoP])) that is needed to combat an attack of a pathogen and therefore the associated lack of specific criteria for product and process for state-of-the-art vaccine development. In addition, several features of vaccines (Table 13.1), such as the low risk-to-benefit ratio as a result of the (predominantly) healthy target population for vaccination, large study populations for efficacy studies as a result of low infection rates, the need for combination vaccines with coming challenges of immunologic and pharmaceutical interference, and the low therapeutic dose and subsequent analytical challenges make

**TABLE 13.1 Specific Features of Therapeutic Biopharmaceuticals and Prophylactic Vaccines**

| | Therapeutic Biopharmaceuticals | Preventive Vaccines | Trend Vaccine |
|---|---|---|---|
| Target population | Patients with specific disease: majority adults and elderly adults | Healthy population: majority infants and children | Toward elderly (including therapeutic vaccines) |
| Acceptable risk-to-benefit ratio | High (depending on disease) | Low | |
| Phase III, number of subjects | 100–1000 | >3000 (depending on incidence of infection) | |
| Therapeutic dose | Milligram range | Microgram range | |
| Number of doses or subject | Multi = regular injections daily or weekly for years | 1–4 | |
| Need for combinations or needle-free delivery | No | Yes | |
| Basis for product target profile | Structure activity relation | Complex immunology: multiple correlates of protection (e.g., T-cell response, systemic B-cell responses, mucosal immune responses) | |
| Average development time | 8–12 years, decreasing | 15–20 years | Shorter for bioterrorism vaccine application without clinical trials |
| "Success rate" | One in six when reaching toxicology studies and clinical trials | Lower than one in 10 when entering clinical studies | |
| Main features bill of testing | PK and PD<br>Repeated toxicology | Efficacy<br>Safety<br>Repeated toxicology | |
| Cost | 1000 Euros per gram | | Increasing in developing world |

PD: pharmacodynamics; PK: pharmacokinetics.

**FIGURE 13.1** Biopharmaceutical product and process development. implementation of current guidelines highly challenging compared with biopharmaceuticals such as mAbs [9].

The classical process development for vaccines has been based on a trial-and-error approach based on the Pasteur principle of isolate, inactivate, and inject [10]. A modification of this early development includes the adaptation of strains to attenuated versions of the pathogen that do not cause the disease but do generate a protective immune response. Examples of attenuated strains for bacterial and viral vaccines against tuberculosis and polio are bacillus Calmette-Guérin (BCG) and Sabin polio virus, respectively. The development of the classical vaccines (DTP-P and mumps, measles, rubella [MMR]) resulted in a black box processes with limited scientific understanding (Fig. 13.1a). This was in the pre-GMP era with considerably lower requirements for process rationale and validation. The production processes for classical vaccines were implemented for genetically stable pathogens with the exception of influenza, which shows yearly seasonal changes [11].

The classical approach starts with the isolation of the pathogen and selection of methods to culture and store it in safe conditions. Then an animal model is used to

demonstrate that the chemical (formalin or β-propiolactone) inactivated pathogen as vaccine induces an antibody immune response and provides protection against the wild-type pathogen in a challenge study. A feasible small-scale production process is developed to produce the inactivated pathogen, and a practical approach is used for scale up for market volume, confirmed by animal studies. Because a vaccine dose contains about 1000-fold less product than required for treatment with therapeutic recombinant proteins, the required increase in production volume and scale is usually smaller.

For bacterial vaccines, a pathogen strain has been cultured and inactivated to produce a "whole-cell" vaccine (e.g., *Bordetella pertussis*), an attenuated bacterium has been used (BCG), or pathogen bacterial strains have been cultured to produce purified and inactivated toxins or virulence factors (*Corynebacterium diphtheriae*, *Clostridium tetani*, *B. pertussis*).

For viral vaccines, usually adherent primary cells were cultured (rat, chicken cells for MMR, eggs for influenza, monkey cells for polio) in glass (Roux) bottles or plastic roller bottles, on membrane plates, and in bioreactors when microcarriers made it possible [12].

Probably because of their proven great beneficial effect for public health and the existing vaccine surveillance programs, monitoring the effect of released vaccines the regulatory agencies have not demanded upgrade of classical vaccine manufacturing to current guidelines. In fact, probably because of the rise of regenerative medicine products (which, besides most vaccines, form another category of "less well-defined" products), the most recent ICH Q11 guideline [7] provides or offers a choice in approach between "traditional" and "enhanced" (with more scientific understanding of product and process) vaccine development approaches.

As opposed to the development of product quality features (critical quality attributes [CQAs]) confirming the process feasibility criteria (design space) for well-characterized biopharmaceuticals, the vaccines, as less defined products, adopted the "process equals product" paradigm [13,14].

The black box status presents the risk that when a pathogen that is considered to be stable will change over decades the existing vaccines will become less effective. This should be observed by the surveillance programs, as seem to be the case for *B. pertussis* [15–17], mumps [18,19], and measles [20–22].

Another risk is that the black box production process cannot be kept constant during half a century of manufacturing, for instance, because of obligate changes in suppliers of raw materials, disposables, and manufacturing equipment. Over the years, minor changes that have no effect on the product efficacy that are accepted could add up to larger process changes yielding a vaccine product with lower efficacy than the original product. This cannot be demonstrated with actual CQA (Table 13.2) of product quality but has to be deduced from the often nonaccurate animal models used as read out for a correlate of protection (antibody titers, pathogen-neutralizing serum titers) and the postmarketing surveillance monitoring.

Many vaccine manufacturers of classical vaccines have already upgraded their production processes by introducing improvements such as the application of serum-free media and the change from primary cells to immortal adherent cell lines.

**TABLE 13.2 The Quality by Design Roadmap for General Pharmaceutical Product Development and Vaccine Development**

HCP: Host cell proteins.

Vaccine development and the vaccine market have seen a revival since the introduction of the pneumococcal conjugate vaccine Prevnar, illustrating that higher cost processes for vaccines are feasible for the developed world. Other factors that have contributed include the threats of pandemics and bioterrorism, development of therapeutic vaccines, and the support of institutions such as the Bill & Melinda Gates Foundation for vaccination in developing countries.

With the introduction of new technologies (Table 13.3), such as conjugate vaccines for bacterial pathogens and VLP vaccine concepts for viral pathogens, more targeted approaches for specific pathogen groups are emerging.

## 13.2 CURRENT VACCINE DEVELOPMENT (PRODUCT AND PROCESS)

For vaccine development, there seem to be two basic strategies: the classical strategy close to the pathogen (isolate, inactivate, and inject) and an alternative strategy to build a vaccine from individual components.

Staying close to the (whole) pathogen, producing an inactivated pathogen product or a less pathogenic attenuated strain (either obtained by natural selection or recombinant method), has a potential benefit of incorporating several unknown epitopes that will support either specific or nonspecific (adjuvants) immune response. The benefit of such potentially broad immunogenic responses might be masked by evasive mechanisms of the pathogen, such as high variability or the presence of components that interfere with the normal immune response.

The other option is to develop a vaccine based on building blocks. Such a vaccine may consist of (recombinant) antigens (e.g., proteins, saccharides, or both) that are formulated as a particulate vaccine. The build vaccine product consisting of (mainly) known components will have a (mainly) known structure–function relationship: each component in combination with the formulation will induce known immune activities to elicit the target immune response defined by the correlates of protection in the target population. This option would be open for fully characterized vaccine products as mentioned earlier and could facilitate a QbD approach for vaccine development.

The current vaccine development seems to favor a "best of both worlds" or hybrid strategy. These options hold that additional information is gathered during the vaccine development trajectory (from literature, "omics," previous projects, or guidelines). Such complex (vaccine) development trajectories ask for an integrated project approach (or multidisciplinary project approach).

The development of a vaccine provides a costly, long-lasting, and complex challenge. To deal with such a complex challenge that requires input from several experts to give target specifications for process and product, the integrated project approach is warranted. In this integrated approach, all of the relevant experts are included in the project team to collect the target criteria and to translate it in a plan with specific criteria for milestone achievements for the different phases of the development.

A vaccine development can fail because of various reasons, such as economic (unacceptable high cost of goods), regulatory (insufficient quality level),

**TABLE 13.3 Classical and New, Improved Vaccine Technologies for Vaccine Development**

| Technologies | Disease | Pathogen | Vaccine |
|---|---|---|---|
| | | *Classical* | |
| Isolate and inactive | Diphtheria | Diphtheria bacteria | Diphtheria toxoid* |
| | Tetanus | Bacillus tetani | Tetanus toxoid* |
| | Polio | Polio virus (3 subtypes) | IPV (Salk) |
| | Whooping cough | Pertussis bacteria | Cellular pertussis vaccine |
| Isolate and adapt | Measles | Measle virus | MMR |
| | Mumps | Mumps virus | |
| | Rubella | Rubella virus | |
| | Polio | Polio virus (three subtypes) | OPV (Sabin) |

| | Meningitis | Meningococcus ACWY | Men ACWY |
| | Pneumococcal-induced pneumonia | Pneumococcus type 7 | PnC-7 |
| | | Pneumococcus type 10 | PnC-10 |
| | | Pneumococcus type 13 | PnC-13 |
| Recombinant or VLP | Hepatitis | HBV | HBsAg* |
| | HPV-induced cancer | HPV cancer | HPV* |
| | Whooping cough | Pertussis bacteria | Acellular pertussis vaccine |

*Vaccine is formulated by adsorption on aluminum particles, alum particles act as adjuvant ($AlOH_3$ or $AlPO_4$)
HBsAg: hepatitis B surface antigen; HBV: hepatitis B virus; HiB: *Haemophilus* influenza type B; HPV: human papilloma virus; IPV: inactivated polio virus vaccine; LAIV: live-attenuated influenza vaccine; Men: Meningococcus; MMR: measles, mumps, rubella; OPV: oral polio virus vaccine; PnC: Pneumococcus; VLP: virus-like particle.

technological (process unreliable, insufficient scientific understanding for appropriate control; instability of product, raw materials, producing organism), or failure in clinical trials (insufficient level of predictability of assays for efficacy). Therefore, it is important that the experts of the project team have final responsibility for their expertise in the development project. It is important that the initial development plan contains all of the criteria from the different kinds of expertise that reflect the best feasible compromise (from current knowledge at that time) and that the project team can reach a feasible compromise on how to proceed when certain criteria linked to milestone achievements are not met. This by accepting a lower performance of product or process than given in the target specifications or invest extra effort in meeting the criterion (or presenting this as advice to higher management).

### 13.2.1 Product Development

The development of a new vaccine product starts with a disease caused by a pathogen that generates an unacceptable disease burden (identifying a therapeutic application for which the immune system can help to fight it). Based on the type of pathogen, knowledge on pathogen–host interaction, knowledge from previous comparable development projects, and the current literature, criteria for the product are defined. The level of detail depends on the existing knowledge on the required immune responses to induce protection; most vaccines primarily aim at eliciting an antibody response, although T-cell–mediated immune responses receive increasing attention.

With existing knowledge, several topics have to be addressed to define the product criteria [9,23,24]. These include the target population that should be vaccinated (e.g., infants, adults, elderly adults, subjects with an underlying disease), the required immune response (systemic or mucosal humoral immune responses, the extent and type of cell-mediated immune responses), the route of administration, the optimal (adjuvanted) vaccine formulation, the optimal vaccination schema (one, two, or more doses at specific time points or after specific periods), the regulatory boundaries (new product or second generation), the known appearance of immune evasion by the pathogen, known or expected safety problems (e.g., vaccine-induced enhanced disease as shown in the 1970s for formalin-inactivated respiratory syncytial virus [RSV]).

Unfortunately, to date, existing knowledge on host–pathogen interactions and the requirements for the optimal immune responses (defined by the correlates of protection in the target population) are too limited to allow a full QbD approach (no defined structure–function relationship).

In general, such concept criteria for the vaccine product [9,23,24] can be given by:

1. Repetitive molecular structures, epitopes that evoke a specific immune response against a pathogen:
   a. B-cell epitopes responsible for humoral antibody responses (adaptive)
   b. T-cell epitopes responsible for T-cell–mediated response (innate; that promote adaptive responses)

2. Pathogen-associated molecular patterns (PAMPs), repetitive molecular structures that evoke a supportive general (innate) immune stimulation effect
3. Do not contain molecular structures that block, reduce, or overstimulate the desired immune response (e.g., unwanted T-help (Th) skewing toward Th2 as is the case of many aluminum-adjuvanted vaccines)
4. Structural features: size, correct presentation of (repetitive) epitopes, stable configuration (chemical and biological stability), correct transport for target tissue
5. Additional safety besides point 3: standard, sterile, no viruses, DNA, endotoxin, HCP, leachables
6. Features that support proper delivery, such as powders with a defined particle size for nasal or pulmonary delivery; formulations with mucoadhesive properties for longer nasal residence time; formulations (coated tablets or antiacid co-delivery) that guarantee integrity of the vaccine during passage of the stomach during oral delivery

### 13.2.2 Product Assays, Correlates of Protection

Process development following QbD principles requires fast, accurate assays to determine product quality and quantity to explore and confirm the design space for a target process. There is considerable discussion on what parameters give appropriate correlates of protection [25] and which fast biochemical assays are good indicators of product potency and can predict performance in animals and in humans [26]. The latter is particularly difficult because there is often discrepancy between results obtained with specific animal models and clinical results in humans. Moreover, similar to humans, animal models give rise to a high level of variation and as such are not good indicators for consistency of the final process and product.

### 13.2.3 Process Development

After definition of the product (and intermediate products) and subsequent specifications, a suitable expression systems can be selected that meets the product criteria (for the whole product or for the different subunits). Emphasis in the QbD approach is on product quality attributes, but for economic reasons, the potential yield is relevant because it will determine part of the cost price. For risk reduction, many pharmaceutical companies favor a proven expression system for a comparable new product.

The different phases include:

- The initial process to support product development, part I (will this process or mainly the used expression system provide a feasible process to meet product criteria: and the reverse, can an alternative expression system with proven performance for other vaccines meet the criteria for product quality?)
- A feasible small-scale target process
- Scale up to pilot, prevalidation studies and reproducibility

- Production for toxicology, clinical phases I and II
- Scale up to market scale, validation (mix down scale + consistency runs)
- Clinical phase III and market launch

***13.2.3.1 Selection of a Suitable Expression System*** For a "close to the pathogen" product, the expression system for the vaccine is usually the pathogen or modified pathogen itself. This means culturing the pathogenic bacteria for bacterial vaccines and culturing viruses in animal cells.

For whole inactivated vaccines such as for whooping cough and for live attenuated vaccine as for tuberculosis (TBC), the culturing of the bacterial pathogens (*B. pertussis* and BCG, respectively) is obligatory, but also for the production of purified inactivated toxins such as for tetanus and diphtheria, the upstream process makes use of the original pathogens from *C. tetani* and *C. diphtheriae*, and no shift has been made to produce these toxins as recombinant in the standard bacterial host *Escherichia coli*. For the conjugate vaccines (*Haemophilus influenzae* type b; pneumococcus; meningococcus A, C, W), the capsular sugar components are derived from the target pathogen, and the carrier protein is the standard tetanus or diphtheria toxoid, the CRM protein from a diphtheria mutant, or OmpB membrane protein from *Neissera meningitidis*. For the viral vaccines as close to pathogen products, replication in mammalian (human) cells is usually required. For original vaccines, animals were used as expression system, such as pox virus in cattle and rabies in rabbits. Even today for some applications of viral vaccines (Japanese encephalitis, Crimean Congo hemorrhagic fever), for fast-track development and manufacturing, mouse brain is used for virus replication. Influenza is traditionally cultured in eggs because of its broad replication ability in mammalian (horse, human) and avian (duck, chicken) cells.

From animals, the culture of viruses went to primary cells and later derived cells with extended but still finite life spans (tertiary monkey cells, human diploid lung cells as MRC-5 and WI-38). From these mortal cells, the developments shifted to immortal cells such as Vero (African monkey) and MDCK (Madin-Darby canine kidney) that are cultured as adherent cells that still have contact inhibition to stop growth at confluency. For many viruses, it was also thought that the orientation of an attached (epithelial) cell was necessary to obtain an appropriate quality and quantity of virus. Vero cells have been approved for polio, rabies, Japanese encephalitis, rotavirus, vaccinia, and influenza. MDCK cells are used for approved influenza with both adherent and suspension cells. Concerns with immortal cells are the risk of tumorigenicity or carcinogenicity and the presence of nonproduct viruses because for a viral vaccine product, it is difficult to reduce contaminating DNA and RNA to a very low level during inactivation of purification without damaging or losing the viral product [27].

The first recombinant vaccine, which is for hepatitis B virus (HBV), was approved for the market in 1986 by Merck Sharp & Dohme (MSD) only 5 years after the introduction of the first recombinant biopharmaceutical, insulin. Although insulin was followed by a stream of other recombinant protein biopharmaceuticals (e.g., tissue plasminogen activator, EPO, mAbs, human growth factor hGF), it took until

1998 until the next recombinant vaccine (against Lyme disease) was launched (by Glaxo Smith Kline [GSK]). Because this product was withdrawn from the market, the only approved recombinant vaccines besides that for HBV are the human papillomavirus (HPV) vaccines (MSD, GSK).

The used expression systems for these VLPs are yeast cells (MSD, *Saccharomyces cerevisiae*, HBV, HPV) and insect cells (GSK, HPV). The current VLP-based vaccines make use of adjuvants based on aluminum and/or monophosporyl lipid A or squalene-based oil-in-water emulsion [9]. Because vaccines often require membrane proteins (or other membrane components), it will be interesting to follow whether the same standard expression systems will be used as for the soluble recombinant protein products (*E. coli*, *Saccharomyces*, *Pichia*, Chinese hamster ovary [CHO]).

***13.2.3.2 Process Development Target Upstream Process*** The selection of an expression system largely determines the upstream process. Despite the broad variation in expression systems for vaccines, there are also a number of common features for the upstream process for vaccine manufacturing.

It starts with the seed lot system: a master and working seed lot(s) to start an expansion of bacteria, cells, or virus. For the preculture expansion, many different—usually disposable—systems are used: agar plates, culture flasks, shake flasks, roller bottles, spinner flasks, plastic bags, and membrane plate systems. The expansion culture is continued until a sufficient volume has been generated for the start of the common upstream production unit, the stirred tank reactor (but different operation regimens exist with respect to medium feed, including batch, fed batch, continuous stirred tank reactor (CSTR) retention of cells (perfusion equipment), stirring [type and number of impellers with and without vortex], pH control, and aeration [headspace, sparging]).

During this bioreactor process, a crude product is generated that can be used for further concentration, purification, and inactivation during the DSP.

***13.2.3.3 Process Development: Downstream Processing*** For the classical (whole) modified pathogen vaccines the DSP is limited to concentration and inactivation of product. With the rise of subunit vaccine products the purification of the subunits and the formation of a complete particle product generates considerable more work for the DSP and formulation groups. Standard purification techniques, used for vaccines and biopharmaceuticals in general, to purify product include centrifugation, filtration (dead-end and tangential flow), precipitation, and column chromatography (SEC, IEC, HIC, IAC). As for the upstream processing, the DSP of vaccines from pathogen disruption until final formulation is more characterized by the different methods than by accepted standardization.

### 13.2.4 Formulation and Vaccine Delivery

The development of a vaccine is highly dependent on tailored vaccine delivery approaches to guarantee broad and strong B-cell and T-cell responses. The design of tailored vaccine delivery approaches has several needs and challenges, such as

restrictions posed by specific target populations, potentials of dedicated stable formulations and devices, and the use of adjuvants. These needs and challenges of tailored vaccine delivery approaches, including the current status and perspectives of vaccine delivery via several routes of administration, are discussed in detail by Amorij et al. [9].

Ideally, a vaccine is a simple and stable formulation that is suitable for convenient administration and provides lifelong immunity against the pathogen. Unfortunately, in the traditional vaccine approach, there was little focus on DSP and formulation development other than concentration of the inactivated or attenuated pathogen.

For most classical whole-cell and whole-virus vaccines, proper products have been delivered because the pathogens are stable and lack immune evasive properties. There was little attention on purification and formulation because the "black box" products worked.

Live-attenuated or recombinant whole-pathogen approaches can be attractive as a fast alternative approach (for the wild type in high containment), but the bonus of having several unknown antigens causing a wanted specific and nonspecific supportive immune response might be accompanied by the presence of molecular structures reducing or exaggerating this response (RSV, severe acute respiratory syndrome [SARS]).

The testing of different adjuvants was limited to testing the effect after mixing of different concentrations with the vaccine product (modified pathogen of purified subunit). Probably the same for combination vaccines: mix and test (in animals).

Despite the successes of the classical vaccines, there is still a number of infectious diseases for which no effective vaccine is available (e.g., HIV, malaria) or for which existing vaccines provide insufficient immunity (e.g., tuberculosis, whooping cough) or are unaffordable for those most in need (e.g., pneumococcal disease). In addition, not only the protective immune response induced by the vaccine determines it success but also the willingness of the public to be vaccinated as well as the availability of vaccine and trained personal to administer of the vaccine. Attention to safety has resulted in the development of safer vaccines (subunit vaccines, which in general are less immunogenic), adjuvants to enhance efficacy and facilitate dose sparing, and the exploration of noninvasive administration approaches.

Key aspects for formulation and delivery that have to be considered in vaccine design are [9]:

- The increase in knowledge (as indicated earlier): Knowledge on identification of immune mechanisms and the definition of clear CoPs and development of robust assays for their determination
- Identification of the optimal delivery of the antigen
  - Specific sites in the body
  - Delivery of the antigen to and activation of relevant immune cells
- The success of (recombinant) subunit vaccines (conjugate and VLP) recombinant proteins: Subunit vaccines are less immunogenic (need adjuvants) and are as more pure product less stable (degradation, aggregation)

- Induction of the desired immune response: Depending on the intrinsic immunogenicity of the antigen and the intended route of administration, an adjuvant (delivery system, immune potentiator, or both) may be selected to steer the magnitude and quality of the innate immune response and the uptake and processing of the antigens by antigen-presenting cells
  - Delivery systems, including nanoparticles, microspheres, liposomes, and VLPs
  - Immune potentiators or modulators, which are compounds that directly activate immune cells through specific receptors or pathways
- Proper formulation of the key component, antigen, and adjuvant in a device or container depending on the intended route and storage conditions
- Design of combination vaccines to minimize the risk of decreased willingness to be vaccinated as a result of increased numbers of injections and bear the risk of pharmaceutical and immunological interference
- Cold chain problems in the developing countries (live vaccines often need to be lyophilized, but with the introduction of subunit vaccines, it became feasible to have stable liquid formulations)
- The increasing number of vaccines in pediatric programs and the wish to combine them (the challenge of formulation of combination vaccines is pharmaceutical and immunologic interference)
- Route of administration: Circumvent the use of needles and specific delivery to specific tissues to increase effectiveness

Better vaccines will be designed in the near future when knowledge on CoPs, optimization of vaccine delivery by administration route, delivery system and immune modulator, and stable formulations are integrated.

## 13.3 SPECIFIC RELEVANT TRENDS

### 13.3.1 Regulatory Quality by Design and Process Analytical Technology

***13.3.1.1 Quality by Design*** The ultimate design of vaccines includes QbD. QbD requires a thorough scientific understanding of all of the CQAs of the vaccine product in order to follow the QbD roadmap for pharmaceutical product development (see Table 13.3). To date, many challenges for vaccine development have to be faced before the first vaccine is fully designed by QbD. These challenges include unknown host–pathogen interactions; definition of *all* CoPs; and understanding of potential side effects of the final product, including vaccine-related PK and PD studies.

For a number of subunit vaccines that go in the direction of "well-characterized product" that have been approved for the market, a QbD approach should become feasible. In this category belong VLPs (HBV, HPV) and conjugate vaccines (Hib, pneumococcus, meningitis). Although a full QbD approach for vaccines is not

possible today by an overall design of the product and processes, an approach that is closest to full QbD is the application of QbD on the several unit steps of the production process. This approach, QbD for nonplatform products and processes typical for vaccines, has been described in the A-VAX case study by the CMC-Vaccines working group (comparable to the A-mAb case) [8]. They described a "toward QbD" approach for development of a fictive vaccine, including USP for (inactivated) polysaccharide, VLP and live virus production, DSP steps, polysaccharide–VLP conjugation, formulation based on lyophilization, and aluminum adjuvant adsorption.

***13.3.1.2 Process Analytical Technology*** The PAT initiative [28] was introduced by the US Regulatory Authority of the FDA to promote scientific understanding of the manufacturing process to improve process control and facilitate fast release based on online monitoring. It was written for the pharmaceutical industry in general, so it is also for chemicals and small molecules as products or for the release of water, raw materials, buffers and culture media, and sterilized items in an autoclave.

Process analytical technology uses QbD as a basal approach. To successfully apply PAT and to be able to indicate the critical process parameters per unit process, CQAs must describe the correct product quality (Table 13.4). The last step for PAT is to identify an online signal that adequately reflects the other critical process parameters within a certain used range for this online measured parameter so that within this range, a product with correct predefined quality is always obtained (to be demonstrated in validation studies).

Main benefits that are usually given for applying PAT include better process understanding, shorter release time between process steps, and to the ability to shift a process in used set points and criteria for specific parameters to other values after approval of the process within the given design space for these parameters.

Because demonstrating successful PAT application requires specific CQA for the (intermediate) product and accurate assays to demonstrate this, the standard use of PAT is limited to well-characterized products. For well-characterized products with fast assays for product quality, it is questionable whether PAT application provides an extra benefit over just applying QbD (see Table 13.4).

For less well-characterized products, it is important to generate a good database for process development with all the process specifications that support a specific outcome such as animal (toxicology) studies and clinical studies. In this case, a design space is actually confirmed by the variation within specs of the product, which is monitored in postmarketing surveillance. If an omics assay program, including genomics or microarray, proteomics (two-dimensional gel electrophoreses (GE), MS), and metabolomics testing, has supported the process development, the outcome of the animal and clinical testing and postmarketing surveillance can be coupled to specific information to generate new CQAs in a parallel or retrospective quality approach. Results can then be used for future process changes (see Table 13.4).

*Process Analytical Technology Case Study* An example of implementation of PAT for a human vaccine process is illustrated by the use of an online near infra red (NIR)

**TABLE 13.4 Main Features of Process Analytical Technology and Quality by Design for Process Development and Their Relation**

| Process Analytical Technology | Quality by Design |
|---|---|
| Online measurement to get fast release of product (intermediate, bulk, final) or raw material, medium, or buffer | Product design approach providing criteria based on scientific understanding<br>Design = prospective approach |
| Usually applied per unit process (step) | Usually applied for the whole product development from knowledge on a disease to a therapeutic hypothesis for cure or prevention to product design (clear structure–function relationship) |
| Online signal should reflect all other critical process parameters | Risk reduction based on knowledge; gives defined criteria per milestone for product and process development |
| Critical quality attributes are required to demonstrate that the chosen online parameters indeed reflect the other relevant parameters within the defined design space → scientific understanding of the process | Definition of control strategy using critical process parameters within design space |
| Could be done as a parallel or concomitant approach | Product quality is guaranteed by design space "product release by design" |
| Primarily process database | Uses (new) knowledge of the disease (host pathogen interaction) and relevant information of product and process from comparable products (PK and PD in humans; product stability) |

PD: pharmacodynamics; PK: pharmacokinetics.

signal for the fermentation step of *Bordetella pertussis* [29]. Here the metabolic status of the bacteria is coupled to the production of the gene cluster containing the relevant virulence factors as demonstrated with array technology. The production of virulence factors serves as a marker for product quality that could be linked to the NiR signal.

### 13.3.2 Comparison with Monoclonal Antibodies

After the discovery of Kohler and Milstein to produce mAbs with murine hybridoma cells, a boost in therapeutic drugs was expected [31]. However, the first generation of murine antibody products failed for therapeutic applications because of an unwanted human immune response against the mouse product and because the role of glycosylation of the antibody was not recognized, causing reduced clinical performance such as rapid clearance from the blood of these intravenously added therapeutic antibodies.

The expression systems were modified to be able to generate fully human antibodies, and new assays were developed for screening the glycosylation pattern

and added to the concept product specifications, bill of testing. After this, the development of humanized antibodies led to the great success of the mAbs as group of therapeutic products [32]. mAbs form a homogeneous group of recombinant proteins. As a result, standardized target manufacturing processes as well as fast-track modular development routes for new mAb products have been established (Fig. 13.1b). The standard manufacturing process for an mAb includes an upstream expansion of suspension cells from the working cell bank using animal component–free medium and fed-batch fermentation in a large-scale stirred tank (10,000 l). The standard DSP contains tangential flow filtration (TFF) or centrifugation as primary recovery followed by protein A and ion exchange chromatography and dead-end filtration for removal of virus and sterile final filtration step. The current standard host cell is the CHO cell line; a few other mammalian-derived suspension cells (hybridoma, myeloma) fit in comparable processes.

The better scientific understanding of essential product features and the experiences from repeated process development for comparable mAb projects have led to better risk management, better process control, and more freedom to operate with respect to process changes. Extensive scientific understanding is built in as a result of extensive experience (and data) with the standard expression system and the well-defined target production process. This in combination with detailed characterization of antibody products that allow demonstration of biochemical equivalence of mAbs (including their impurity profile) supports that a process change will not give rise to increased safety risks. Together with the use of a standard expression system—CHO cells on a standard animal component–free medium—with a target production process that was approved for another mAb product supports that the impurity profile of the mAb product will not cause increased safety risk after the process change.

This freedom to operate for process changes has been facilitated by the regulatory authorities such as the FDA. The FDA's point to consider on mAb manufacture and testing [33] includes a section on demonstrating product comparability related to manufacturing changes. If convincing *in vitro* evidence of product comparability (biochemical equivalence) can be provided in combination with data that animal testing reveals no differences, extensive clinical data demonstrating equivalence may not be necessary. The Guidance for Comparability states: "The manufacturer's ability to establish sensitive and validated assays for characterizing the product and biological activity and to evaluate the significance of differences noted in such cases can provide the basis for FDA to assess product comparability without the necessity of repeating clinical efficacy studies" [3].

The extensive scientific understanding of mAb products and their production processes has led to companies specialized in development and manufacturing of new therapeutic mAbs. Most of those companies offer fast-track development of mAbs from (provided) mAb-encoding cDNA to production of the mAb product for clinical phase I trials within 1 year. Others make use of the freedom to operate by first using a transient expression system with insect cells or Human embryonic kidney (HEK) 293 cells for fast product screening and later transferring the product DNA to a CHO cell line.

The scientific understanding, as is the case for mAbs, helps to fulfill a regulatory requirement by giving the rationale why a product contains specific features or why a specific process step is performed in a specific manner. In addition, scientific understanding provides better product performance, improved process control, and databases for troubleshooting ability. This presents a general driving force to acquire the same level of understanding for vaccines as for most other biopharmaceuticals. Unfortunately, this is extremely challenging for vaccines because current knowledge on immunology of host–pathogen interaction and working mechanism of existing vaccines, especially the markers that predict protection by a vaccine (CoPs), is still evolving and limited. As a result, current vaccine development is not possible via full QbD (Fig. 13.1c) and builds on knowledge from general science and previous comparable projects. To add understanding of product and process, vaccine development applies on omics tools (explained later) and other PAT tools.

The fact that many pathogens are highly variable or have other ways to deceive the immune system prevents successful application of the classical Pasteur approach of injecting a whole inactivated pathogen as vaccine. For these pathogens, fundamental research is needed to elucidate the exact host–pathogen interaction in order to be able to "design" a suitable vaccine strategy or to screen vaccine candidates from a reverse vaccinology approach [11] (see Section 13.3.2.1). In recent years, considerable progress has been made in the understanding of the pathogen–host interaction, in particular with respect to the innate immune system (e.g., Toll-like receptor activation). It has become clear that all adaptive immune responses are initiated by the innate immune system and that the recognition of common microbial components by specific receptors is a first crucial step for the response. This has opened the way to a rational design of adjuvants [9,34–36].

***13.3.2.1 Omics*** The availability of high-throughput technologies to sequence genomes of pathogens made a holistic approach for vaccine development possible. This approach, indicated as reverse vaccinology [37], can be used to identify suitable epitopes or antigens for a vaccine. This has been applied for the development of a meningococcus B vaccine by Novartis. The *Neisseria* genome was sequenced and the structural genes suitable for production in *E. coli*, identified as genes encoding for outer membrane proteins, were selected for a after round of testing an immune response. For meningococcus B, the serum bactericidal assay is an accepted correlate of protection to evaluate a protective antibody response against *Neisseria meningitis* type B. Five proteins were selected to be incorporated in the final vaccine product. In recent years, this omics approach has been extended to the more scientific knowledge–based systems biology approach, also called systems vaccinology [38,39], which (preferentially) makes use of markers of the innate immune response in humans to predict the appropriate vaccine (protective) effect [39].

### 13.3.3 Enabling Technologies

A number of technologies have become available for the (general) development of biopharmaceuticals that enable the call for more scientific understanding and

reduction of risk while not causing extra overall development time. In this way, the development of vaccines adopts more generic methods and avoids the "tailor-made" development of specific technologies that is associated with the very long (>15 years) development time of several vaccines a decade ago.

***13.3.3.1 Disposable Technology*** The use of disposable technology can significantly reduce the investment in time and cost to select, implement, and validate stainless steel hardware.

The use of disposable technology is not new. For the freezing of cells in cryotubes; expansion of cells and bacteria in plates, shake flasks, roller bottles, and spinner flasks; and the use of membranes, hollow fibers, and other filters, many disposables items were already available. More recent trends include the use of bags on shaking platforms and disposable bioreactors for the expansion of larger culture volumes and the fermentation process. Also, for DSP, a trend is clear toward the use of disposable filter material.

***13.3.3.2 High-Throughput Technology*** There has been considerable development to create miniature systems to generate scientific understanding faster. This can include the screening for cell lines or particular culture media in multiwell systems or the exploration and confirmation of critical process parameters in downscaled multireactor systems (in parallel testing from one inoculum) or automated DSP systems (automated serial column settings). Usually, design of experiments is used in these multi-experiment systems to reduce the number of required experiments to generate sufficient scientific understanding to define the design space for a specific process step.

In addition, many high-throughput developments have been realized for assay applications facilitating process development (not further discussed here).

***13.3.3.3 Platform Technology*** Platform technology is technology that is already available to use because it has been developed for a group of products that are sufficiently comparable to allow a general approach. For fast development of a process for a new product, it is highly beneficial if there is already a target process using platform technology for several, if not, all unit process steps because it greatly reduces the required time for the process development, and the risk of failure is greatly reduced (provided the products are sufficiently similar).

If for a new product it is feasible to use an existing large-scale reactor for the fermentation process, it saves the time in selecting, purchasing, implementing, and validating the new bioreactor. In addition, there will exist a database on used conditions for several cell lines that can be used for the new expression system, and there is usually a proven downscaled bioreactor system that can be operated under comparable conditions as the large-scale bioreactor, which greatly supports the process development for this process step and reduces the risk for process transfer and scale up. Blueprints for process validation are available, and there is experience with the (nonspecific) in-process controls associated with operating the system. If the same expression system in standardized culture medium is used for a new

comparable product, it is great advantage in knowledge of the impurity profile associated with this production method.

For a product group such as mAbs, there are targeted or modular approaches that only use platform technology. This enables the development of a suitable cell line from cDNA containing the antigen in 3 to 6 months and the generation of material with a standardized process according to cGMP guidelines after another 6 months [7,28].

Risks of the use of platform technology include that different process steps are usually optimized to give an acceptable (feasible with other criteria) value not necessarily the optimal performance, and if a certain technique is used for too long, there might be new, better platform technology (applied by competitors). In this way, use (addiction) of platform technology can slow down improvements in process technology for vaccine development and manufacturing.

### 13.3.4 Emergency Vaccine

The national health agencies of all countries have preparedness for outbreaks of infectious diseases in their standard programs. The preparedness includes all measures to take during an outbreak to try to control the epidemic, such as stockpiling of syringes, antivirals, antibiotics, and potential cross-protective vaccines; reducing traveling; and closing schools. The fast development and production of a vaccine to control are often also included in the scenario [40].

This provides quite a challenge for vaccine development because a fast-track route with minimum risk and maximum predictability has to be provided, which cannot be given for vaccines in general. In the past, little outbreaks have been dealt with successfully by means of producing a vaccine, as tried for HIV and SARS. A successful example of outbreak control by a vaccine the application of a monovalent outer membrane vesicle (OMV) vaccine against meningitis type B in Cuba, Norway, France, and New Zealand.

Key elements for such an emergency vaccine route are:

1. Fast-track development, including proven platform technology
2. Proper correlates of protection
3. A fast-track release schedule, including risk assessment

Because there are few proven routes for vaccine development, a targeted approach for an emergency vaccine would include the traditional Pasteur principle of isolate, inactivate, and inject, ideally combined with QbD-oriented routes. At present, QbD-oriented routes for emergency vaccines against (pandemic) influenza have been applied successfully for related pathogens. In this targeted approach, only unit processes are improved that would block the development and manufacturing. For similar risk reduction for animal studies, several suitable models should be available for testing. Crucial is also a fast-track decision tree for approvals of vaccines by the government, possibly outside the normal regulatory authorities.

The optimum situation is to have a modular approach (fast-track scenario) for specific groups of pathogens that would give a high chance of success to deliver a vaccine fast for an outbreak of a related pathogen. Such a "tunnel" for vaccine development, regulatory approval, and manufacturing exist only for the classical variations of influenza virus.

It is important to update the strategies when new proven routes, such as the targeted approach for conjugate vaccines, have become available. Because the outbreak control is a public responsibility but vaccine manufacturing is a private enterprise, a proper interface between governmental agencies and (local) vaccine companies is essential.

## 13.4 FUTURE TRENDS FOR VACCINE DEVELOPMENT

An increase in vaccine development activities is expected for "the decade of vaccines" (Gates), driven by both public and private investments and promoted by the increased understanding of the immunology of vaccines. As is described in ICH Q11, it is expected that the classical route will be chosen for attenuated of inactivated modified (whole) pathogen vaccines in addition to the structural (or QbD-like) approach for well-characterized subunit vaccines. Both development routes will improve to reduce the risk of failure of the development project.

The classical approach is expected to improve by:

1. Partial characterization of the complex product (by omics)
2. Better selection of relevant animal models such as specific disease animal models that mimic human disease or show a more human-like immune responses to a pathogen
3. Improvement of human correlates of protection
4. A properly defined production process according to PAT to improve the definition of products that are not fully defined

The more current structural—or QbD-like—approach based on scientific understanding of product and process will further gain importance with the increase in knowledge of immunology and the findings from many vaccine developments (either successful or not).

It would also be beneficial to gain knowledge for future approaches by analyzing the way the classical vaccines work.

For successful application of a structural approach, endproduct criteria have to support the different aspects of the whole process (or design space, see figure 13.2) because the weakest (unknown) link will reduce the predictability of vaccine development. Therefore, an integrated approach using input from different relevant experts seems to be the best approach for vaccine development in the near future. In this way, vaccine development might be faster in the near future than pathogens are able to develop their modes of deceiving our immune systems.

**FIGURE 13.2** The design space as a subspace of the investigated space (also known as the knowledge space). The operating space (where the process is intended to run) can be a large or small part of the design space. (Adapted from Ref. [30].)

# Role and Application of Adjuvants and Delivery Systems in Vaccines

RAJESH K. GUPTA

## 14.1 INTRODUCTION[1]

Adjuvants have been described for use with vaccines for almost a century [1–4]. The word "adjuvant" is derived from the Latin word *adjuvare*, which means to help. Therefore, the term "adjuvant" has been used for any substance or material that helps vaccine antigens induce an early, high, broad (providing cross-protection against different variants or strains of the pathogen), or longer lasting immune response (Table 14.1) [5–18]. Adjuvanted vaccines often require less antigen to achieve a protective immune response, thus extending availability of vaccines to a larger population, which is important during pandemics and vaccine shortages. Although the mechanisms of most commonly evaluated adjuvants have not been fully understood, the adjuvant effect or adjuvanticity of these substances was considered to be (1) by modulation of immune system (e.g., activation of cells of the immune system); (2) by targeting of antigens to antigen-presenting or other immune cells; or (3) by controlled delivery of antigens, including slow-release or depot formation, at the site of injection. Because of the broad definition of adjuvants and the lack of a clear understanding of mechanism of action (MOA) for most commonly used adjuvants, many diverse substances that, when added to vaccine antigens, result in an increased immune response to vaccine antigens have been considered as adjuvants. The increase in immune response by certain substances could be attributable to stabilization of the antigen from degradation or by facilitating complete delivery of antigen to subjects by preventing antigens from being adsorbed onto the final container or syringe used for delivery of vaccines. Such increases in

**TABLE 14.1 Role of Vaccine Adjuvants and Delivery Systems**

| |
|---|
| Enhance the immune response (higher antibody levels) |
| Develop an early and longer lasting protective immune response |
| Develop a broad immune response providing cross-protection against related strains |
| Develop protective immune response with lesser antigen, reducing the cost and increasing availability of vaccines to broader population |
| Facilitate development of combination vaccines by avoiding antigen competition, carrier specific epitope suppression, original antigenic sin, and so on |
| Modulate immune response to desired type, cellular (MHC class I) or humoral (MHC class II) |
| Modulate immune response to appropriate T-helper cells Th1, Th2, or other types to elicit appropriate response against a defined pathogen |
| Modulate antibody avidity, type (isotype, IgG subclass) |
| Elicit immune response in immunologically hyporesponsive populations such as elderly, immunocompromised, and pediatric populations |

MHC: major histocompatibility complex.

immune response should be considered as a formulation aspect in the development of vaccines and distinct from true adjuvant effect. Until the past two decades, not much attention was paid to the formulation during development and manufacture of vaccines, with the exception of the development of optimal formulations to maintain virus viability in live viral vaccines suitable for freezing or lyophilization.

As with most discoveries in medicine, use and development of adjuvants have been empirical without knowledge about the mechanism of adjuvanticity. Use of aluminum-based adjuvants in human vaccines started in the 1920s and 1930s as alum was originally used to partially purify protein antigens, mainly tetanus and diphtheria toxoids, by precipitating them in the presence of anions, including phosphate, sulfate, and bicarbonate ions, resulting in a mixture of compounds, mainly aluminum sulfate phosphate and aluminum hydroxyl phosphate [4,19–25]. Under specific conditions of pH and ionic strengths, these toxoids bound or adsorbed onto the aluminum compounds and were separated from other impurities. Over the years, several MOAs for aluminum-based adjuvants have been proposed, which is discussed later in this chapter. However, the role of aluminum-based adjuvants is still not clear.

Because of the importance of adjuvants in human vaccines established by the widespread use of vaccines with aluminum-based adjuvants and because of limitations of these adjuvants [6,19,20], there has been a search for alternate safe and potent adjuvants for more than 50 years. This became important and necessary with the development of purified, subunit, and synthetic vaccines, which are poor immunogens and require potent adjuvants to provide protective immune response. Furthermore, interest in development of new adjuvants grew because of their potential to selectively modulate the immune response to Th1 or Th2 types by directing antigen presentation through major histocompatibility complex (MHC) class I or MHC class II [7,26]. Selective modulation of immune response is

considered important for certain vaccines eluding successful development, for example, vaccines for protection against certain infectious diseases (e.g., respiratory syncytial virus, human immunodeficiency virus [HIV], malaria, tuberculosis), cancer, fertility, and allergenic and autoimmune diseases.

## 14.2 CHALLENGES IN DEVELOPING VACCINE ADJUVANTS

Despite advances in our knowledge about the immune response to infections, diseases and vaccination, and a better understanding in the MOA of various adjuvants, mineral compounds (mainly aluminum adjuvants) continued to be the only adjuvants used with human vaccines for almost a century. The development of adjuvants for human vaccines has been one of the slowest progresses in the history of medicine [27]. However, during past two decades, vaccines against influenza, hepatitis B virus (HBV), and human papilloma viruses (HPVs) have been approved in the Europe, the United States, and other countries with new adjuvants, such as oil-based emulsions and combination of oil-based emulsions, aluminum adjuvants, and monophosphoryl lipid A (MPL) [14,16,18].

There are a number of challenges in the development and use of adjuvants for human vaccines. The biggest problem with the use of adjuvants for routine vaccines are toxicity and adverse side effects after vaccination [6]. Because routine vaccines are given to healthy individuals, any side effect or even the perception of a side effect is not acceptable. An adjuvant for routine immunization of healthy infants, children, and adults must have a very low or no adverse side effects. Severe side effects, even those occurring rarely, would not be acceptable for routine vaccines unless there was a clear benefit against burden from disease and no other treatment alternatives are available for the indication for which the vaccine is given. When a new vaccine is introduced, there are often clear and visible benefits of a vaccine against morbidity and mortality of the disease (high risk). But as the vaccine continues to be used and controls the disease successfully (low risk of disease burden with the use of vaccine), the public forgets about the burden from the disease and remembers only side effects, even if they are rare and may not be caused by the vaccine. Thus, the success of a vaccine becomes an impediment for its continued use. There have been many examples of increase in disease burden with decrease in vaccination rates caused by adverse publicity against vaccines [28,29]. As our knowledge in immunology and vaccinology continues to grow, there is a need for continuous improvement in existing vaccines and adjuvants to stay ahead of the declining risk-to-benefit ratio for diseases controlled by vaccination.

At present, the choice of adjuvants for routine human vaccines reflects a compromise between a requirement for adjuvanticity and an acceptable low level of side effects. For high-risk groups such as patients with cancer or AIDS or for therapeutic vaccines, a certain level of toxicity may be acceptable based on benefits. However, the development of adjuvants for such applications has been challenging to get an appropriate immune response that could provide required protection or treatment for these diseases, which do not yet have successful vaccines. Other

problems in the development of adjuvants have already been discussed in several publications [7,10,13], which include restricted adjuvanticity of certain formulations to a few antigens, use of aluminum adjuvants as reference adjuvant preparations under suboptimal conditions, nonavailability of reliable animal models for most diseases, use of nonstandard assays, and biological differences between animal models and humans. These problems may lead to the failure of promising formulations to show adjuvanticity in clinical trials and delay advances in development of adjuvants.

## 14.3 VACCINE ADJUVANTS, ADJUVANT EFFECT, AND TOXICITY

Adjuvants belong to a heterogenous group of chemical compounds with diverse MOAs [5,7,8]. This is clearly evident from substances described as adjuvants for the first time in 1926 by Ramon showing increased antitoxin response to tetanus and diphtheria toxoids [2,3]. These substances included agar, tapioca, lecithin, starch oil, saponin, and even breadcrumbs. Major mechanisms of adjuvanticity are summarized in Table 14.2. However, it is not easy to categorize adjuvants on this basis because of multiple MOAs proposed for many adjuvants. Furthermore, because of the empirical development of vaccines and adjuvants with an emphasis on developing a formulation that works, several adjuvant preparations contain multiple substances to form complex formulations with an objective to elicit optimal immune response. For example, Freund's complete adjuvant (FCA) is an oil-based vehicle and contains *Mycobacterium* as a potent immunostimulator [30]; Syntex adjuvant formulation (SAF) contained threonyl muramyl dipeptide (MDP) as an immunostimulator and oil and pluronic block polymers as vehicles; certain liposome formulations contained encapsulated MDP, MPL, or cytokines and aluminum compounds; and GlaxoSmithKline (GSK)'s proprietary adjuvant systems (AS) contain combinations of aluminum compounds, oil-based components, and immunostimulators [14,18].

Because of a broad definition of adjuvants in helping to increase the immune response to an antigen, another aspect of adjuvant effect has been modification of

**TABLE 14.2 Major Mechanisms of Actions by Vaccine Adjuvants**

| Mechanism | Examples |
|---|---|
| Depot formation | Mineral compounds, oil-based adjuvants, liposomes. biodegradable polymer microspheres $>10\ \mu m$ |
| Delivery vehicles and targeting immune competent cells | Liposomes, oil adjuvants, biodegradable polymer microspheres $<10\ \mu m$, nanoparticles, non-ionic block polymer surfactants |
| Modulation of response (activation of immune-competent cells) | Lipid A, monophosphoryl lipid A, cPG, QS21, pertussis toxin, cytokines |

antigen in a controlled manner, resulting in an enhanced immunogenicity for that antigen. Modifications of antigens to increase their immunogenicity include (1) polymerization of protein antigens (tetanus toxoid and diphtheria toxoid) by glutaraldehyde treatment [31–33], (2) cationization of proteins (diphtheria toxoid) [34], and (3) conjugation of proteins to haptens and polysaccharides [7]. Primarily, conjugation is done to provide T-cell-dependent antigen characteristics to haptens and polysaccharides by proteins [35–37]. Carrier proteins, when coupled to T-cell-independent antigens, haptens, or weak immunogens, enhance the immunogenicity of the antigens coupled to these proteins. Carrier proteins usually act by providing T-cell epitopes to the coupled antigens or by increasing the molecular weight of the antigen. Carrier proteins are immunogenic to themselves, and it was observed that if the conjugation between polysaccharides and proteins is performed carefully without destroying important epitopes on a carrier protein, polysaccharides also enhance immunogenicity of the proteins [7]. This aspect is important in the development of combination vaccines to avoid problems with antigen overload and carrier-specific epitope suppression. As discussed earlier, any substances contributing to stabilization and protection of the antigen from degradation or preventing antigen from adsorption to the final container or syringe used for delivery of vaccines, thus ensuring complete delivery of antigen, may also have been considered an adjuvant. It is suggested that such enhanced immune response by modification or stabilization of antigens should not be considered an adjuvant effect.

During the past 50 years and even earlier, several adjuvant formulations were developed, and a few of them were evaluated in clinical trials. Most of them were never used for routine vaccines either because of lack of adjuvanticity or their toxicity and side effects. Because adjuvanticity is often associated with adverse side effects, a balance between these two attributes has to be maintained to obtain a defined or clear benefit for the use of an adjuvant. Some of the adverse effects are ascribed to mechanisms involved in the adjuvanticity of these formulations. For example, local reactions may be attributable to depot formation at the site of injection, which is one of the mechanisms of adjuvanticity of several adjuvant formulations (Table 14.2). Another mechanism of adjuvant action is stimulation of cells of the immune system to secrete various cytokines that may lead to systemic side effects depending on the type and magnitude of the cytokine response. Other side effects may be attributable to general adverse pharmacologic reactions of various formulations.

## 14.4 CHARACTERISTICS OF AN "OPTIMAL" ADJUVANT

With our current knowledge about the immune system, it seems that adjuvanticity and toxicity or side effects are integral parts of the adjuvant formulation. Depending on the required risk-to-benefit ratio, a balance between adjuvanticity and side effects can be optimized, particularly when using a rational design in development of vaccines. Theoretically, an ideal adjuvant without any side effects is desirable. Because of safety concerns of the adjuvant formulations for prophylactic vaccines,

particularly for routine immunization of infants and children, Edelman [5,10] listed a number of criteria to ensure the safety of adjuvanted vaccines. In addition to safety of adjuvanted vaccines for the absence of local reactions, systemic reactions (general toxicity, pyrogenicity), autoimmune diseases, hypersensitivity reactions, carcinogenicity, teratogenicity, and so on, an ideal adjuvant would be chemically defined so that it can be manufactured consistently. The preparation would elicit a protective immune response with a variety of weak antigens and would allow use of lower doses of antigens, achieving protection with fewer injections. The adjuvant would be effective in infants and young children, ideally at birth, and would also be effective in hyporesponsive population such as elderly and immunocompromised patients. The adjuvant would elicit a more persistent response of high quality (high affinity antibodies or desired IgG isotype) and breadth covering cross reacting strains of pathogens and of desired type (humoral, cellular, local, or systemic). The adjuvant would be stable with regard to adjuvanticity and toxicity with no or minimal interaction with the antigen. It would be biodegradable and nonimmunogenic to itself. However, there will never be a single adjuvant having all of these characteristics; however, there are possibilities to develop an adjuvant with the required characteristics based on risk-to-benefit ratio and striking a compromise or balance between desired and nondesired characteristics.

Even with the development of an optimal or ideal adjuvant with no toxicity and desired adjuvanticity, the adjuvant should only be used with vaccine antigen if it is required for effectiveness and safety of the product or provides a clear or distinct benefit. The need and benefits of using an adjuvant with a vaccine should be demonstrated in humans because animal models have not been good predictors of effectiveness of most human vaccines. This requires an extra group in clinical trials for the vaccine without an adjuvant. For traditional vaccines, aluminum adjuvants have been used by convention based on adjuvanticity in animals, sometimes without a clearly demonstrated enhanced immune response or protection in humans. It may be possible that aluminum adjuvants have been stabilizing the formulation, thus indirectly contributing to enhanced immune response.

## 14.5 REGULATORY ASPECTS FOR ADJUVANTS USED IN HUMAN VACCINES

Adjuvants are not licensed per se for use in humans; rather, they are approved as part of a vaccine formulation. However, it is generally mentioned or discussed at various meetings and in publications that aluminum-containing adjuvants have been the only adjuvants licensed by regulatory agencies. Adjuvants are not and should not be licensed alone for use with any vaccine because their physicochemical characteristics, such as size of particles and surface charge on the adjuvant, change after mixing antigen with or adsorbing antigen onto an adjuvant, particularly for aluminum-containing adjuvants. Such changes in physicochemical properties have the potential to affect the adjuvanticity and safety profile of the adjuvanted or adsorbed formulation. It is essential to know the chemistry,

manufacturing, and control aspects, including the toxicity, of an adjuvant intended for use with a vaccine. It may be of value to perform extensive toxicology and pharmacology studies on the adjuvant alone to learn about this material. However, such studies may not truly represent the toxicologic and pharmacologic profile of the vaccine formulated with adjuvant. Historically, toxicology studies performed typically for drugs have not been performed for vaccines because vaccines are given in minute amounts (microgram quantities) in only a few doses spread over several months. However, in recent years, typical toxicology studies performed for drugs have been recommended and required for vaccines. These studies may be useful for certain vaccines, adjuvants, or vaccine formulations, but there must be a scientific basis for performing extensive standard toxicology studies for vaccines. In a recent toxicology meeting, a concern about the immunotoxicity of adjuvanted vaccine formulation observed during toxicology studies was raised. This clearly shows a lack of scientific or regulatory understanding because vaccines and adjuvants are designed to modulate or elicit an immune response, when such response for a therapeutic drug is immunotoxicity, but is required for efficacy of the vaccine.

Historically, specific safety tests were designed and routinely performed at various stages of vaccine manufacture based on science; perceived risks; and the knowledge of the microorganism, attenuation history, inactivation, and so on. These tests were specifically designed to include susceptible animal species (e.g., guinea pigs for tetanus and diphtheria toxicity and detection of risk of tuberculosis for vaccines made from monkey cells, monkeys for neurovirulence test of oral polio vaccine, rabbits for detection of cercopithecoid herpesvirus 1, adult mice for detection of lymphocytic choriomeningitis virus, suckling mice for detection of *Coxsackie* viruses), or other systems (cell cultures from monkeys and humans to detect a number of simian and human viruses, rabbit kidney cells to detect herpes virus), appropriate doses (five human doses for residual toxins in tetanus and diphtheria vaccines), duration (6 weeks for specific toxicity test for diphtheria), appropriate stage of manufacture (adventitious agents and *Mycoplasma* testing on products made from cell cultures during early stage of manufacture, such as control cells and viral harvests), and route of inoculation (intraperitoneal, subcutaneous, intraspinal, intracerebral) rather than one or two standard animal species (mice, rats, rabbits) in an acute or chronic toxicity tests. Similar safety testing should be designed for the evaluation of novel adjuvants, including testing of raw materials, the adjuvant itself, and the formulated product. Testing should be based on perceived risks and science rather than only performing standard toxicology studies. If there is a scientific rationale to perform standard acute, chronic, reproductive, carcinogenic toxicology studies, these must be performed.

Because adjuvants are desired to be active components in a vaccine formulation, these should be manufactured and characterized like an active component. Dose of vaccine antigen and immunization schedule are based on the efficacy and effectiveness of the formulation, including the adjuvant. The formulated product should be fully characterized, and the consistency in manufacture of the formulated product should be demonstrated with regard to various characteristics, such as size of

particles, degree of adsorption or encapsulation, amount of active components of adjuvant, and so on.

## 14.6 ADJUVANTS USED IN LICENSED VACCINES

Until almost two decades ago, aluminum compounds were the only adjuvants used with human vaccines. Calcium phosphate has been used as an adjuvant with a number of vaccines, mainly in France, but has not been in use for many years. During the past two decades, several vaccines with other adjuvants have been approved or licensed for human use (Table 14.3). These include influenza vaccines with an alternate adjuvant system, oil-in-water emulsions (MF-59 and AS03), and HBV and HPV vaccines with a combination adjuvant formulation composed of MPL and aluminum hydroxide (AS04), all of which have been approved in Europe, and HPV vaccine with AS04, which is licensed in the United States [14,16,18]. Other adjuvants that have been used with approved human vaccines include virus-like particles (self-assembling particles composed of one or more viral protein); for example, immunopotentiating reconstituted influenza virosomes are registered as a component of the hepatitis A vaccine in Europe, Asia, and South America.

### 14.6.1 Aluminum Compounds

Aluminum compounds, including aluminum hydroxide ($Al[OH]_3$), aluminum phosphate ($AlPO_4$), a mixture of these compounds, and alum-precipitated vaccines, have been the most commonly used adjuvants with vaccines [19–25]. For inactivated and subunit vaccines, aluminum adjuvants are usually the first choice because of their good safety track record, low cost, and adjuvanticity with a variety of antigens. These adjuvants are often referred to as "alum" in the literature and during discussions at scientific and regulatory meetings, which is misleading because alum, chemically

**TABLE 14.3 Adjuvants Used in Licensed Vaccines**

| Adjuvant | Vaccine | Usage |

| Virosome (liposome) | Influenza<br>Hepatitis A virus | Europe |

DTP: diphtheria, tetanus, pertussis vaccine; HBV: hepatitis B virus; HPV: human papillomavirus; MPL: monophosphoryl lipid A.

potassium aluminum sulfate ($KAl[SO_4]_2 \cdot 12H_2O$), is not an adjuvant as such; and two commonly used aluminum adjuvants, referred to as "alum", aluminum hydroxide and aluminum phosphate, have very different physical characteristics [24,25] and differ in their adjuvant properties [20–22]. Alum was originally used to partially purify protein antigens, mainly tetanus and diphtheria toxoids, by precipitating them in the presence of anions, including phosphate, sulfate, and bicarbonate ions, resulting in a mixture of compounds, mainly aluminum phosphate sulfate or aluminum sulfate. Such vaccines were called "alum-precipitated vaccines," which led to the use of term "alum" for describing vaccines with aluminum-containing adjuvants [19–25].

Alum-precipitated tetanus and diphtheria toxoids were the first routine human vaccines using aluminum adjuvants and were used for human immunization for many years [7,19]. Although "alum" was not the adjuvant in these vaccines, the use of these preparations left a legacy for the term "alum," which has been used to describe all aluminum-containing adjuvants. The legacy of this inaccurate description seems to be in part contributing to our lack of understanding about the use and MOA of these adjuvants, leading to describing all adjuvants as a "dirty little secret" [38]. Researchers and industry may be responsible for maintaining the "dirty little secret" status for aluminum adjuvants by upholding the tradition and convenience of referring to all aluminum-containing adjuvants as "alum" despite differences in physicochemical and adjuvant properties and the MOA of aluminum hydroxide and aluminum phosphate. Perhaps because of proprietary reasons for keeping vaccine formulations secret or because of a lack of clear understanding of the science, aluminum adjuvants have been incorrectly or incompletely described in several vaccines formulations. For example, certain vaccines described to be adsorbed on aluminum hydroxide actually have aluminum hydroxyphosphate in the final formulation. This happened because phosphate buffer used in the formulation converted aluminum hydroxide to aluminum hydroxyphosphate by ligand exchange mechanism [39–41], either before or when antigens were added to the adjuvant.

The stability, potency, and immunogenicity of certain vaccines, particularly those with ligands, such as phosphate groups in HBV and *Haemophilus influenzae* type b (Hib) conjugate vaccines, that can exchange with the hydroxyl group on aluminum hydroxide, depend on mechanism and strength of binding of antigens to the aluminum adjuvant [25,40,41]. Antigens with phosphate groups bind through a covalent bond to aluminum hydroxide by the ligand exchange mechanism. Such a binding is so strong that bound antigens are not immunogenic, which may be attributable to distortion of secondary and tertiary structure of antigens bound chemically to aluminum through ligand exchange mechanism. It may also be possible that protective epitopes on antigens chemically bound to aluminum adjuvants are not presented to B cells or such antigens are not able to get processed by dendritic or other antigen processing cells. When a formulation starts with an aluminum hydroxide adjuvant and a phosphate buffer is used during formulation, the original aluminum hydroxide adjuvant immediately becomes aluminum hydroxyphosphate because of ligand exchange mechanism. In such a formulation, the

antigen with ligands that can exchange with hydroxyl group cannot replace the phosphate group. Such formulations are stable and immunogenic.

Use of alum-precipitated vaccines declined considerably because of variability in production of such formulations and the development of defined and controlled aluminum hydroxide and aluminum phosphate preparations [7,19,20,42–44]. Because aluminum compounds have been widely used for so many years with human vaccines, they have become the benchmark or reference for evaluating new adjuvant formulations. It is very important to prepare optimal formulations of vaccines adsorbed onto aluminum adjuvants in order to correctly evaluate new adjuvants. Two methods have commonly been used to prepare vaccines and toxoids with aluminum compounds—an *in situ* precipitation of aluminum compounds in the presence of antigen (developed originally to purify toxoids by precipitation with alum) and adsorption of antigens onto a preformed aluminum gel [5–7,19–23,42–44]. Adsorption of antigens on aluminum adjuvants depends on the physical and chemical characteristics of the antigen, type of aluminum adjuvant, and conditions of adsorption. These conditions are often not adequately described in publications or not optimized, resulting in poorly formulated aluminum adjuvant preparations that do not exhibit optimal adjuvanticity.

Another complexity in understanding the MOA of aluminum adjuvants is considering aluminum phosphate, aluminum hydroxide, and all of the vaccine formulations containing these adjuvants similar. Characteristics of aluminum adjuvants, for example, their physical structure being crystalline or amorphous, size of the gel particles, adsorption capacity, point of zero charge, ratio of aluminum to phosphate, and so on depend upon the conditions of making these gels, including the order of adding reagents, speed at which the reagents are added and mixed, mixing speed, time taken to adjust pH, and scaling up the production [20–23,25,44]. Such variables, if not controlled, affect batch-to-batch consistency of the adjuvant; therefore, aluminum adjuvants have been described as difficult to manufacture in a physicochemically reproducible way. However, over the years with the implementation of current good manufacturing practices (cGMP) to the vaccine production industry, manufacture of aluminum adjuvants has been standardized, and consistency in manufacture has been demonstrated within a manufacturer. But there may still be a high degree of heterogeneity in physicochemical properties of aluminum adjuvants from various manufacturers. Physicochemical properties, including the size of gel particles and charge of the adjuvanted vaccine, quality (strength), and quantity (degree of adsorption/binding) of antigens adsorbed onto the adjuvant, are distinct for each product, which may have an impact on the adjuvant properties and MOA [25,40]. The physicochemical properties for the same vaccine (e.g., a simple adsorbed tetanus toxoid) will be different for different manufacturers because of heterogeneity in quality of aluminum adjuvant and different formulation conditions. It will not be surprising then to find a different MOA for a vaccine antigen adsorbed onto different aluminum adjuvants or the same aluminum adjuvant under different conditions. For example, activation of immune competent cells may depend on an overall charge and other characteristics of the vaccine formulation, and the size of gel particles may lead to either depot formation for a formulation with large particles

**TABLE 14.4 Important Characteristics and Parameters for Adsorption of Antigen onto Aluminum Adjuvants**

| Characteristic or Parameter | Optimal Conditions |
|---|---|
| Ligand exchange (ions or groups on antigens, e.g., phosphate) | Avoid ligand exchange between antigen and adjuvant<br>Use phosphate buffer with aluminum hydroxide for antigens with ligands for potential exchange |
| Electrostatic forces (charge on antigen and adjuvant) | Opposite charge on antigen and adjuvant at pH for formulation |
| Hydrophobic interactions | |
| Van der Waals forces | |
| Hydrogen bonding | |
| pH | 6.0–7.5, at optimal pH adjuvant and antigen with opposite charges |
| Temperature 4–25°C | Depending on the stability of antigen |
| Size of gel particles | $<10\,\mu m$ |
| Ionic strength of reaction mixture | Low, absence of phosphate ions for aluminum phosphate |

($>10\,\mu m$) or direct delivery to macrophages or dendritic cells for a formulation with small particles ($<10\,\mu m$). In many publications, the MOA of aluminum adjuvants has been evaluated by using the aluminum adjuvant alone or the type of aluminum adjuvant is not specified, often referred to as "alum." Because of the different physicochemical properties of an aluminum adjuvant alone and vaccine formulated with the aluminum adjuvant, the MOA may be different for various preparations. Therefore, it is expected that there are a number of hypotheses, sometimes conflicting, about the MOAs of aluminum adjuvants (discussed later).

The characteristics and parameters affecting the adsorption of antigens onto aluminum adjuvants are summarized in Table 14.4. The adsorption of antigens onto aluminum adjuvants depends heavily on the electrostatic forces between adjuvant and antigen and ligand exchange [24,25,39–41]. Adsorption based on electrostatic forces is a preferred method, and ligand exchange, in general, between adjuvant and antigen should be avoided. Other interactions, including hydrophobic, van der Waals, and hydrogen bonding, contribute to the adsorption of antigens on aluminum adjuvants. However, these forces may not suffice to cause adsorption of antigen if the same charge or electrostatic repulsive force is present on antigen and adjuvant. The two most commonly used aluminum adjuvants (aluminum hydroxide and aluminum phosphate) have different points of zero charge [25]. At neutral pH, these gels have opposite charges, wherein aluminum phosphate is negatively charged and aluminum hydroxide is positively charged. It is important to select the aluminum adjuvant carefully on the basis of the charge of the antigen at neutral pH or any other desirable pH. Other physical conditions affecting adsorption of antigens on mineral adjuvants include pH, temperature, size of the gel particles, and ionic strength of the reaction mixture. Whereas the pH and ionic strength affect adsorption by altering

charge on the gel and the antigens, the temperature may affect the rate of interaction between the gel and the antigen. The size of gel particles affects the surface area of gel available for adsorption: small particles have more surface area than large particles. For example, the amount of diphtheria toxoid adsorbed onto aluminum hydroxide gels was inversely proportional to the gel particle size [45].

An acidic pH of less than 6 has been commonly used for adsorption of tetanus and diphtheria toxoids onto the aluminum phosphate adjuvant [42] because diphtheria toxoid and aluminum phosphate are both negatively charged at neutral pH, resulting in poor or no adsorption. At a pH of 6.0, aluminum phosphate is positively charged, thus improving adsorption of negatively charged diphtheria toxoid. *In situ* adsorption of diphtheria toxoid resulted in higher adsorption than the commercial aluminum phosphate preparation, probably because of trapping of some antigen in the gel [20–22]. Adsorption of tetanus and diphtheria toxoids onto aluminum hydroxide gel (Alhydrogel) was not sensitive to the pH commonly used in formulation of these vaccines (pH 6.0–7.0) and to excess phosphate ions because aluminum hydroxide is positively charged and toxoids are negatively charged at this pH range [20–22]. Adsorption of bovine serum albumin onto aluminum hydroxide or lysozyme onto aluminum phosphate was inversely proportional to their ionic strength [46]. Excess anions, particularly phosphate ions, and impurities, such as amino acids, peptides, and polysaccharides, reduce protein adsorption, probably by competing with antigen for adsorption sites [47]. Multiple-charged negative ions, especially phosphate ions, interfere with the adsorption capacity of aluminum hydroxide because of conversion of aluminum hydroxide to aluminum hydroxyphosphate and therefore affecting its charge. These negative ions may be used for elution of adsorbed antigens from the gel. Lindblad and Sparck [47] recommended avoiding phosphate buffers in the reaction mixture for adsorption of antigen onto aluminum adjuvants, but use of phosphate buffer has been helpful in avoiding binding of certain antigens to aluminum hydroxide by a ligand exchange mechanism. In general, a low ionic strength and absence of excess phosphate ions and impurities are recommended for optimal adsorption of antigens on aluminum phosphate gel [48].

It is recommended that each formulation be evaluated and optimized for adsorption. Although it may be beneficial to have maximum adsorption of antigen to the adjuvant, binding by ligand exchange mechanism may be detrimental to the immunogenicity and effectiveness of many antigens. The temperature of adsorption has been considered important for complete adsorption of antigen onto aluminum phosphate, although most of the adsorption, up to 80 to 90% of diphtheria toxoid, occurred within a few minutes at temperatures ranging from 4 to 45°C [42]. There has been some discussion on desorption of antigen from adjuvant after injection into the body when a physiologically neutral pH and presence of body fluids containing proteins and anions might desorb the antigen from the gel. Earlier studies showed that freshly made preparations of aluminum phosphate adsorbed diphtheria toxoid had more antigen desorption than aged preparations when exposed to neutral pH or serum [42]. Thus, aging of aluminum-adsorbed vaccines appears to improve their immunogenicity [43].

The MOA of aluminum-containing adjuvants is still not clearly understood despite their extensive use in human vaccines for almost a century [49,50]. A number of mechanisms have been proposed over the years for the adjuvant action of aluminum-containing adjuvants, starting with a concept of depot formation at the site of injection. Glenny et al. [51], who first described and used aluminum adjuvants, proposed in 1931 that aluminum adjuvants act by depot formation at the site of injection, allowing for a slow release of antigen and thus prolonging the time for the interaction between antigen and antigen-presenting cells (APC) and lymphocytes. The local depot mechanism was challenged when Holt [43] observed that antibody formation continued after removal of the adjuvant–antigen depot from the site of injection. In another study, the depot formation could not be confirmed, when approximately 90% of radiolabeled tetanus toxoid adsorbed onto aluminum phosphate disappeared from the site of injection within 24 hours of subcutaneous injection, but tetanus toxoid encapsulated within biodegradable polymer microspheres stayed at the site of injection for prolonged periods [52]. However, the amount of aluminum phosphate adsorbed tetanus toxoid at the site of injection was higher than the soluble tetanus toxoid for 4 weeks, thus demonstrating some localized depot formation. The depot concept, which is still considered one of the mechanisms for aluminum adjuvants, has generated numerous discussions. Is it a short-term depot, to which macrophages are attracted, or a long-term depot from which antigen is released over an extended time? There are also questions regarding site of the depot. Is it formed at the site of injection or in the draining lymph nodes? These questions remain unanswered with evidence to support or contradict these theories. White et al. [53] showed that antibody-producing cells in the regional, popliteal lymph nodes of rabbits injected with 150 Lf of soluble diphtheria toxoid completely disappeared in 3 weeks, but rabbits injected with 10 Lf of aluminum phosphate precipitated toxoid had antibody producing cells in the nodes at 3 to 4 weeks, suggesting a depot in the draining lymph nodes. The most direct evidence for a local depot effect comes from experiments in which local granulomas, formed after injection of aluminum-adsorbed vaccines, were able to induce immune responses when these granulomas were excised from the site of injection 7 weeks later, macerated, and injected into other animals [54]. The antigen in the granuloma was apparently not available to the animals for a secondary response because minute doses of antigen injected adjacent to the granuloma produced a secondary antibody response [55]. White [55] postulated that antigen within the granuloma was unable to penetrate the fibrous tissue surrounding the granuloma, and antibody may be reacting with antigen to form an antigen–antibody precipitate within the fibers of the peripheral zone of the granuloma, thus preventing the diffusion of antigen from granuloma and sequestering it from APC.

Another hypothesis on the MOA of aluminum-containing adjuvants has been considered as their potential to target APC. The adjuvanticity of mineral adjuvants may be due to their ability to convert soluble antigens to particulate forms, which are more readily phagocytosed. The particle size of commercially available aluminum adjuvant gels is less than 10 μm, the average size for aluminum hydroxide, Alhydrogel was 3.07 μm and for aluminum phosphate, Adju-phos was 4.26 μm.

It has been shown that polylactide glycolide (PLGA) microspheres smaller than 10 μm are taken up by APC and provide strong adjuvant effects [56]. The size of aluminum adjuvant particles changes after adsorption of antigens onto the adjuvant and over time when adsorbed vaccines are stored. So this hypothesis of targeting to APC will be different for various formulations depending on the size of particles in the formulation. Antigen adsorbed onto aluminum hydroxide is more readily taken up by human monocytes than free antigen, and human monocytes exposed to aluminum hydroxide secrete interleukin-1 (IL-1) [57]. The adjuvanticity of aluminum gel particles via targeting to APC emphasizes the importance of degree of adsorption of antigens onto gels. However, it has been reported that antigens partially adsorbed onto aluminum-containing adjuvants are as effective as those with complete adsorption.

Activation of the immune system by aluminum-containing adjuvants has also been discussed as a possible MOA. An increased antibody response to a soluble antigen has been observed when aluminum adjuvant was injected at a different site, suggesting a systemic stimulatory effect on immunocompetent cells, possibly mediated by cytokines [58]. However, these results were not confirmed in a subsequent study, when antibody responses of mice to diphtheria toxoid and aluminum hydroxide injected at different sites versus soluble diphtheria toxoid alone were very low and similar, even after 2 doses [20]. Aluminum compounds have been reported to induce eosinophilia [59] and activate complement [60], which may lead to a local inflammatory response, thereby enhancing the antibody response. It was also shown that mice injected with alum (aluminum hydroxide) with or without antigen had an increase in IL-4–producing cells bearing the monocyte and neutrophil marker $Gr1^{+}$(5) [61]. Mineral adjuvants augment mainly humoral immune response, particularly IgG1 and IgE antibody responses, through IL-4 [62] by activation of Th2-type cells [8,63]. This type of immune response is similar to that elicited by most soluble protein antigens. Cooper [63] described aluminum adjuvants as good stimulants for Th2-type cell-mediated immune response, especially eosinophils, which is similar to that elicited by some helminth parasites [44]; thus, aluminum adjuvants may be a good candidate for antiparasitic vaccines. In a special mouse hybrid model of schistosomiasis, Horowitz et al. [64] demonstrated protection in animals injected with sonicated parasite antigen and aluminum hydroxide. In contrast, antigen injected with FCA elicited lower IgE antibodies and lower levels of protection. Aluminum adjuvants are not efficient in raising cell-mediated immune responses [8,65]. The induction of delayed type hypersensitivity by aluminum adjuvants in mice and guinea pigs has not been clearly demonstrated [48,66].

Lately, there has been much attention in understanding the MOA of aluminum adjuvants, the most used adjuvant in the history of vaccination [25,27,30,49,50]. During the past 10 years, there have been a number of reports on the mechanism of adjuvanticity for aluminum-containing adjuvants at the molecular level. Tritto et al. [49] suggested two independent mechanisms of adjuvanticity for aluminum-containing adjuvants: (1) presenting antigen in a particulate multivalent form to APC, thus enhancing immunogenicity and (2) promoting a local proinflammatory

environment by Toll-like receptor– (TLR-) independent mechanism, which results in blood cell recruitment and dendritic cell differentiation. However, the molecular target for alum proinflammatory activity is still unknown [49].

Recent data from different laboratories demonstrated that the molecular target for aluminum-containing adjuvants is nucleotide binding and an oligomerization domain (NOD)-like receptor protein 3 (NLRP3) [49,67–69]. NLRP3 interacts with the apoptosis-associated speck-like protein containing a caspase recruitment domain, ASC, and the protease caspase 1 to form a protein complex called inflammasome. When the inflammasome is activated, it processes proinflammatory cytokines, including IL-1β, IL-18, and IL-33, into their mature form. *In vitro*, alum activates caspase 1 through NLRP3 and synergizes with TLR agonists such as lipopolysaccharide for IL-1β production [67,68]. This process is blocked by actin polymerization inhibitors, indicating that NALP3 activation requires phagocytosis [67]. It was further demonstrated that NLRP3 activation contributed to alum adjuvanticity when antibody responses to a number of antigens adjuvanted with alum were significantly reduced in NLRP3-deficient mice compared with wild-type animals [68]. In an another study, Th2 cell priming and antibody responses to ovalbumin or human serum albumin co-administered with alum were impaired in NLRP3-, ASC-, or caspase 1–deficient mice [70]. These data could not be reproduced because human serum albumin injected with alum to NLRP3-deficient mice showed comparable antibody responses to those elicited in wild-type animals, suggesting that NLRP3 is not required for alum adjuvanticity [71]. These conflicting data might be the result of different immunization routes and different protocols for measuring the immune response [49].

Another hypothesis on the adjuvanticity of aluminum-containing adjuvants is based on activation of NLRP3 through the induction of necrosis, which causes the release of danger signals such as uric acid and adenosine triphosphate [72,73]. A higher concentration of uric acid was observed locally after alum administration in the peritoneum, and uricase treatment decreased T-cell priming induced by alum, suggesting that uric acid release at injection site is required for alum adjuvanticity [72]. However, necrosis, as a mechanism of alum adjuvanticity, was not supported by *in vitro* data showing that macrophage treatment with uricase does not affect the response to alum [68,70]. Furthermore, Flach et al. [74] also suggested that this may not be possible because alum injection triggered a mild tissue irritation, suggesting little cell death or uric acid release. However, more insights on activation of NLRP3 by alum came from Hornung et al. [75], who showed that phagocytosis was essential for NLRP3 activation and IL-1β release by alum, silica crystals, or fibrillar amyloid β. A recent report showed that alum interacted with membrane lipids on the surface of dendritic cells, triggering signaling cascades that promote $CD4^+$ T-cell activation and humoral immune responses [50].

It seems that the mechanism of adjuvanticity for aluminum-containing adjuvants is far from clear [49,50] despite a clear understanding of the physicochemical properties of aluminum-containing adjuvants [24,25,39,40], description of various hypotheses on the adjuvanticity [27,49,50], and an optimism that adjuvants are no longer a “dirty little secret” because of an increase in our understanding of innate

immunity [16,26,38]. This may be due to a unique MOA for every aluminum adjuvant-containing formulation, as discussed earlier, or there may be other possibilities. Aluminum-containing compounds have been shown to be potent adjuvants in various animals models, particularly in rodents, mice, and guinea pigs, with a number vaccine antigens, especially tetanus and diphtheria toxoids [76,77]. Their role in providing enhanced antibody response in humans has been questioned for tetanus and diphtheria vaccines from time to time, indicating that these adjuvants may not be potent adjuvants in humans. Despite a lack of an understanding about the MOA, it is clear that aluminum adjuvants have an important role in the effectiveness of existing vaccines. One of the roles that aluminum adjuvants may have in the enhanced immune response of many vaccines could be their ability to stabilize vaccine formulations and ensuring the complete delivery of vaccine antigen dose. Because vaccines are used in minute amounts (microgram quantities), there is a possibility of a small but significant amount of these active ingredients lost because of protein aggregation or binding on the surface of delivery containers, such as vials and syringes. Aluminum adjuvants provide stability to certain antigens when adsorbed on to them and additionally ensure complete delivery of small amounts of antigens because antigens, when not formulated with aluminum adjuvants, can adsorb on the surfaces of containers. This role in helping vaccine antigens may be considered as adjuvant effect within the broader definition of adjuvants, but this is a formulation issue, which can also be achieved by developing alternate formulations.

The enormous heterogeneity in physicochemical properties of vaccines formulated with aluminum-containing adjuvants, leading to a chaos in our understanding of their MOA, has an advantage in the flexibility in designing these adjuvants to characteristics required for a specific formulation. By carefully adding varying amounts of phosphate to aluminum hydroxide, a formulation of aluminum hydroxyphosphate having zero charge at the desired pH between 5 and 10 can be achieved. This type of formulation work will lead to rationale design of vaccines with aluminum adjuvants. Such formulations, with varying amounts of phosphate buffer added to aluminum hydroxide to optimize the adjuvanticity, have been developed empirically without understanding the science involved in the conversion of aluminum hydroxide to aluminum hydroxyphosphate, thus changing mechanism of antigen binding to the adjuvant. Such well-characterized formulations may help in our understanding of the MOA of aluminum adjuvants, taking advantage of all the knowledge and tools gained over the years in understanding aluminum adjuvants.

Despite so much confusion about the adjuvanticity of aluminum-containing adjuvants, these adjuvants have been in use for almost a century and will continue to be used with currently licensed vaccines and new vaccines because of their long track record of use, low cost, and extensive experience in manufacture of these products. With enhanced understanding of the physicochemical characteristics of aluminum compounds and flexibility in modulating these characteristics to manage the quality and quantity of binding or adsorbing vaccine antigens onto these adjuvants, a rationale design in developing vaccines with these adjuvants is possible and desirable. This will enable a better understanding of the MOA of these

adjuvants and ensure control over manufacturing process to achieve consistency in manufacture.

### 14.6.2 Oil Emulsions

Another class of adjuvants used with human vaccines intermittently for almost 50 years is oil emulsions, which also have a long history of use with animal vaccines [78–81]. Almost a century ago and before aluminum adjuvants were described, Pinoy and Le Moignic [1] in 1916, reported that a suspension of killed *Salmonella typhimurium* in mineral oil increased the immune response. Later, in 1925, Ramon [2] described starch oil as one of the substances augmenting the antitoxic response to diphtheria toxoid. The oil emulsions as adjuvants did not receive further attention until Freund [30] in 1937, demonstrated the adjuvant effect of mineral (paraffin) oil mixed with killed *Mycobacteria*, referred to as FCA. FCA has been one of the most potent adjuvants described so far and has been used extensively to augment the immune response of laboratory animals mainly in generating hyperimmune serum. However, its use in animals has been banned or restricted for several years because of immense suffering and pain to animals. FCA has been too toxic to be used in humans.

The water-in-oil emulsion without *Mycobacteria*, called Freund's incomplete adjuvant (FIA), has been used in a number of veterinary vaccines [78–81]. FIA was used in humans with influenza and killed poliomyelitis vaccines, enhancing the immunogenicity of these vaccines [82–87]. The MOA of FIA was attributed to depot formation at the site of injection and slow release of antigen with stimulation of antibody-producing cells [88–90]. Use of FIA was discontinued in humans because of the side effects such as local reactions at the site of injection (granuloma and cyst formation), oil-induced neoplasms in mice, and Arlacel A induced carcinogenicity in mice [91,92]. Nevertheless, FIA-based influenza vaccine produced fewer side effects than aqueous vaccines [83] probably because of use of less antigen with this adjuvant and also because of the slow release of antigen from the adjuvanted vaccine. Hundreds of thousands of doses of FIA-adjuvanted vaccines had been inoculated into humans before the possibility of carcinogenicity was raised based on a study in mice. A long-term follow-up of the subjects injected with FIA-adjuvanted vaccines failed to show an increase in mortality, tumors, or autoimmune diseases caused by oil adjuvants [93]. The FIA-based bacterial vaccines such as cholera [94] and tetanus [95] produced better immunity than aqueous preparations, but side effects, including sterile abscesses, ulcers, and delayed-type local reactions, were recorded. These severe local reactions were considered to be attributable to the presence of lipopolysaccharide (LPS) in cholera vaccine and to certain enzymes in the bacterial vaccine components that degraded the Arlacel A to release toxic fatty acids [96–98]. Based on severe local reactions and the possibility of carcinogenicity as observed in mice, it was concluded that the use of mineral oil adjuvants in the human population may be hazardous and should not be recommended for general use in humans [92,99].

In search of an alternate adjuvant to FIA, various kinds of emulsions with different oils were evaluated to develop a stable, nontoxic, and effective adjuvant for human

vaccines. Hilleman and colleagues described an oil-based adjuvant, "Adjuvant 65," consisting of 86% peanut oil, 10% Arlacel A (the ester mannide monooleate) as the emulsifier, and 4% aluminum monostearate as the stabilizer [82,100]. Unlike FIA, this adjuvant contained an oil component, which was metabolized or excreted by the body. In humans, Adjuvant 65 was safe and potent but exhibited less adjuvanticity than FIA. Nevertheless, the use of Adjuvant 65 was discontinued because of reactogenicity in humans with certain lots of vaccine and a reduction of adjuvanticity when a purified or synthetic emulsifier was used in place of Arlacel A [101]. Different emulsions such as oil-in-water and water-in-oil-in-water emulsions using other oils, including sesame oil and peanut oil, were also tried as adjuvants, but none of these emulsions has been used for routine human vaccines [102–108].

During the 1980s and early 1990s, several reports described oil-in-water emulsions using squalene or such emulsions with emulsifiers, surfactants, or immunomodulators to stabilize the emulsion or enhance the adjuvanticity of the formulation [109–112]. The emulsifiers commonly used to stabilize oil-in-water emulsions included fatty acid esters of polyhydric alcohols such as Tween and Span series. Synthetic organic surfactant adjuvants used with squalane-in-water emulsion were the block polymer surfactants [111]. Immunostimulators used in oil-in-water emulsions included MDP and its derivatives, trehalose dimycolate (TDM) and MPL, with or without emulsifiers or non-ionic block copolymer surfactants [109–114]. It was suggested that antigen should be incorporated into the internal phase of oil emulsions for an effective adjuvanticity (e.g., the water phase of water-in-oil emulsion and the oil phase of oil-in-water emulsion) [110].

During the early 1990s, an oil-in-water emulsion named MF-59 containing 4.3% squalene (w/v), 0.5% Tween 80 (w/v), and 0.5% Span 85 (w/v) was developed by scientists at Chiron Vaccines. This emulsion gave consistently higher antibody levels to a variety of antigens in animals and humans than aluminum adjuvants [16,115–118]. Early toxicology studies of MF-59 in animals and in humans demonstrated its safety with vaccines against herpes simplex virus (HSV), HIV, and influenza virus. MF-59 has been shown to be a stimulator of both humoral and cellular immune responses to subunit antigens in animals as well as humans. Based on early radiolabeled studies, it was suggested that MF-59 does not appear to act by depot formation [16]. In a recent article [118], the MOA of MF-59 has been proposed from all the work performed on this adjuvant. It has been described that MF-59 creates a transient "immunocompetent" local environment at the injection site, resulting in the recruitment of key immune cells, which take up the antigen and the adjuvant and transport them to the local lymph nodes, where the immune response is induced. It seems that MF-59 induces local cells to create chemokine-driven gradient, which recruits immune cells to the injection site.

Inactivated influenza vaccine with MF-59 has been licensed for more than 10 years in Europe and has been administered to more than 50 million people worldwide with a good safety record [16,116,117]. The development of MF-59 over many years shows challenges in developing vaccines in general and adjuvants in particular. Successful development of MF-59 adjuvant was possible because of the persistence and patience of the Chiron scientists in developing this formulation and because of

lessons learned from failures and setbacks in evaluating various formulations for more than 20 years [16]. Originally, Chiron Vaccines developed an oil-in-water emulsion as a delivery system for an immunostimulator called MTP-PE, a synthetic version of MDP [115]. In clinical testing, this formulation showed high reactogenicity for use with routine vaccines [119,120]. So this formulation was another failed attempt to develop a vaccine adjuvant because of safety problems. Further evaluation of this formulation showed that the emulsion vehicle alone, without the immunostimulator, was an effective adjuvant [121]. The emulsion alone (MF-59) showed an adjuvant effect with inactivated influenza vaccine with no additional benefit of MTP-PE. Exclusion of MTP-PE prevented significant and unacceptable local and systemic reactions. These observations led to development of MF-59 as a stand-alone adjuvant for influenza vaccines [122], which has benefits of extending the supply of influenza vaccine during a pandemic because of use of a lower vaccine dose. Furthermore, MF-59 has been shown to induce cross-protective immune response against divergent strains, which is important both for pandemic and seasonal vaccines [116,117]. MF-59 has been effective in elderly adults as well as infants who are most vulnerable to influenza and respond poorly to influenza vaccines [16].

Other lessons learned by Chiron scientists during development of MF-59 included importance of selection of appropriate antigen, good trial design, and relevant immunologic endpoints for the success of a vaccine [16]. A good adjuvant cannot compensate for poor selections in these areas.

Initially, the MF-59 adjuvant might be perceived to have "failed," but what really failed were the assumptions on which the vaccine candidate was based. For example, MF-59 was used with HSV vaccine in a phase III efficacy trial for protection against genital herpes simplex infection, and the vaccine failed to offer sustained protective efficacy [123]. The same vaccine formulation had also failed to show efficacy as a therapeutic vaccine candidate in a previous trial [124]. The adjuvant, MF-59, was selected because of its ability to induce high levels of neutralizing antibodies and T-cell responses, and the adjuvant achieved that with the HSV vaccine [125]. It was found that serum-neutralizing antibodies did not offer protection against HSV infection, which is a sexually transmitted disease, for which there is often repeated exposure of high viral load [126]. There are additional examples in which MF-59 performed as expected, but a vaccine antigen or the concept was not appropriate. MF-59 has induced potent neutralizing antibody responses against HIV gp120 envelope [127] and high levels of protective titers against hepatitis B surface antigen [128]. However, the antibody responses induced against HIV gp120 were not able to neutralize relevant "field" strains, which has been a problem for all HIV vaccine candidates evaluated so far. Therefore, a good adjuvant cannot fix a bad antigen and cannot compensate for an incorrect assumption in a clinical trial design [16].

Another oil emulsion–based adjuvant licensed in Europe with inactivated influenza vaccines is GlaxoSmithKline's AS03, which is a combination of α-tocopherol (vitamin E) and squalene in an oil-in-water emulsion with a droplet diameter of approximately 150 nm [14,18,129]. Vitamin E is known to have immune-enhancing properties and maintains the integrity of cellular membranes by protecting their physical stability [18]. Both monocytes and macrophages respond to AS03 with a

local production of a range of cytokines and chemokines. An AS03-adjuvanted pandemic influenza vaccine has allowed for antigen sparing with a high level of cross-reactive immune response to heterologous strains of H5N1 [130–132]. Both the MF-59 and AS03 adjuvant formulations are designed to mix at the time of use, which provides flexibility in the use of adjuvant. This has raised a question about regulatory agencies approving an adjuvant alone, which can be used with an approved vaccine. An approved vaccine must be evaluated with an already approved adjuvant for another vaccine for its safety and efficacy. As discussed earlier, mixing of an antigen and adjuvant may create a unique formulation with distinct physicochemical and adjuvant characteristics depending on the nature and characteristics of the antigen. Therefore, licensing of an adjuvant will not represent the safety profile of the adjuvant when formulated with a particular vaccine antigen. When a vaccine is licensed as two separate entities or components, vaccine antigen and adjuvant, which are mixed immediately before use, consistency in physicochemical characteristics and the safety and stability of the emulsion for a few hours (e.g., up to 6 hours) must be demonstrated for the mixed product.

### 14.6.3 Other Adjuvant Systems Used in Licensed Vaccines

Liposomes have been around for almost 40 years [133] and have been evaluated extensively as adjuvants for the last 30 years, alone as delivery vehicles or for targeting antigens to APC, as well as in combination with other immunostimulators, such as MDP, LPS, lipid A, MPL, QS-21, and so on [16–18,133–139] Liposomes are typically made up of concentric lipid membranes containing phospholipids and other lipids in a bilayer configuration separated by aqueous compartments. These were originally developed to be used as carriers of biologically active substances and have been safely administered parenterally to patients as carriers of therapeutic drugs without formation of granulomas at the site of injection. They acted as adjuvants in a number of animal studies with a variety of antigens. Both humoral and cell-mediated immune responses have been augmented by liposomes [140]. Not only is the clearance of antigens incorporated into liposomes markedly prolonged, but the liposomes may also target antigen to APC, including macrophages. The cell-mediated immunity is believed to be stimulated because of the hydrophobic nature of liposomes. Adjuvants such as LPS, lipid A, MPL, and MDP when incorporated into liposomes had better adjuvanticity and less toxicity [138]. Nonphospholipid liposomes (Novasome vesicle) have been used commercially for two poultry vaccines approved by the US Department of Agriculture. These nonphospholipid liposome vesicles were evaluated with human vaccine antigens (tetanus and diphtheria toxoids) in rabbits and mice [139]. Two common approaches to formulate antigens with liposomes include adsorption on its surface or entrapment inside the liposomes [17]. Tetanus and diphtheria toxoids encapsulated in or mixed with these liposomes elicited antitoxin levels similar to those elicited by antigens given with FCA or adsorbed onto aluminum adjuvants [139].

Another type of liposome, referred to as virosomes or fusogenic liposomes, is created by inserting virus fusion proteins into a liposome bilayer [141]. Virosome-based

influenza and hepatitis A vaccines have been licensed for human use in Europe for more than 10 years [16,17,142]. These products have been shown to be well tolerated and immunogenic in all age groups, including elderly adults, adults, and children. The suggested MOA of influenza-based virosomes involves a direct interaction of virosome particles with APC or, in some cases, with B cells, which in turn, activate T cells. Despite the limited use of virosome-based vaccines in Europe, liposomes have not been used for routine human vaccines. However, in recent years, a number of liposome-based therapeutic vaccines, particularly against cancer, have been evaluated [143–145].

Combination of two or more adjuvants has been evaluated in the past in animals and in human clinical trials. During the last 10 years, two vaccines, hepatitis B vaccine and HPV vaccine, with a combination of two adjuvants, MPL and aluminum hydroxide, named AS04, were approved for human use [14,16,18]. MPL, a derivative of the bacterial cell wall LPS, is a potent immunostimulant. The adjuvant effect of LPS was described in 1956 [146], although it was known earlier that certain Gram-negative bacteria or vaccines from these organisms had an adjuvant effect [6]. LPS and MPL activate TLR-4, a receptor expressed on APC [26,49]. The engagement of TLR-4 promotes cytokine expression, antigen presentation and migration of APC to the T-cell area of draining lymph nodes, allowing for an efficient priming of naïve T cells.

Most of the biological activities, including adjuvanticity and toxicity, of LPS are due to lipid A region of the molecule [147,148], thereby making LPS and lipid A too toxic for use in human vaccines. Incorporation of LPS or lipid A into liposomes reduced the toxicity while retaining or even increasing the adjuvant effect [138]. Attempts have been made to detoxify LPS without affecting its adjuvanticity. The most promising derivative of lipid A, which has been shown to have most of the adjuvant properties of LPS but with markedly diminished side effects, is MPL [149–152]. The lower toxicity of MPL compared with LPS has been ascribed to the removal of one of the phosphates on lipid A. However, when lipid A was completely dephosphorylated with hydrofluoric acid, the dephosphorylated preparation still had same amount of pyrogenic activity in rabbits as the lipid A (Gupta, R., unpublished data). During preparation of MPL by mild acid hydrolysis of lipid A from *Salmonella minnesota*, one or two fatty acid chains on lipid A backbone bound by ester bond are also removed along with one phosphate group. Normally, lipid A with complete toxicity and adjuvant properties has six or seven fatty acid chains. Lipid A with less than six fatty acid chains has demonstrated significantly less toxicity and pyrogenic activity while retaining some of the adjuvant activity of unmodified lipid A (Gupta, R., unpublished data). The balance between toxicity and adjuvanticity of MPL without one phosphate group and fewer than six fatty acid chains makes it suitable for human use as compared with the toxicity–adjuvanticity balance of lipid A and LPS.

In AS04, MPL is adsorbed onto aluminum hydroxide or aluminum phosphate, depending on the vaccine and its desired adsorption [153,154]. MPL activates the innate immune by directly stimulating TLR-4, leading to maturation of dendritic cells and the expression of cytokines that enhance the adaptive immune response by stimulating the maturation of Th cells to the Th1 type. Thus, the recognition of MPL

by TLR-4 leads to enhanced humoral and cellular immune responses. The aluminum adjuvant appears to modulate and prolong the cytokine responses to MPL at the injection site. These results support a model in which addition of MPL to an aluminum adjuvant enhances the vaccine response by prompting increased activation of APC and stimulation of Th1-type responses [155].

AS04-adjuvanted HBV vaccine significantly enhanced the immune response to hepatitis B antigen and induced rapid, higher, and longer lasting seroprotection and enhanced cell-mediated immune response compared with aluminum-adjuvanted vaccine for prehemodialysis and hemodialysis patients, who are relatively poor responders to aluminum-adjuvanted HBV vaccine [156], Similarly, the AS04-adjuvanted HPV vaccine induced higher antibody levels compared with the same antigen formulated with an aluminum adjuvant. Furthermore, the AS04-adjuvanted HPV vaccine provides cross-protection against certain other high-risk HPV types not contained in the vaccine [157].

## 14.7 FUTURE DIRECTIONS AND PROSPECTS

For more than 50 years, a number of novel adjuvants have been evaluated with human vaccines in preclinical and clinical studies. Before the past two decades, aluminum adjuvants were the only adjuvants used with routinely administered human vaccines. During the past 20 years, the licensure of a number of vaccines with alternate adjuvants has renewed optimism and enthusiasm in the development of novel adjuvants.

Expanded knowledge about pathogenesis and protection from diseases, either after a natural infection or against early vaccines, containing whole organisms (inactivated or live attenuated) and purified or partially purified virulence factors has led to an understanding about recognition of pathogen-associated molecular patterns (PAMPs) by the immune system through pathogen-recognition receptors, including the TLRs, NLRs, and RIG-I-like receptors (RLRs) [26]. Most currently used vaccines made from whole organisms and virulence factors of pathogens, including detoxified toxins, have inherent adjuvanticity due to PAMPs that can bind various receptors. For example, bacterial cell walls, peptide sequences in toxins and other virulence factors, DNA, and viral RNA commonly present in current vaccines can bind specific TLRs and activate the TLR-expressing APC. Such an understanding of innate immune responses and their impact on modulation of B- and T-cell responses facilitates the development of adjuvants with the potential to modulate the quality and quantity of immune response with an acceptable risk-to-benefit ratio for the particular indication for which the adjuvant is being developed.

With the growing knowledge of the innate immune system and a better understanding of mechanisms of adjuvanticity and toxicity of various adjuvants, it seems possible for novel vaccines to be rationally designed or tailored when the benefits outweigh the risk. For example, a low- or weakly modulated immune response for a prophylactic vaccine and a strongly modulated immune response for a therapeutic vaccine against cancer or HIV with a high risk and higher benefits will both be acceptable and desirable.

## ADDENDUM

When this chapter was being drafted, there were initial reports of rise in cases of narcolepsy among children and adolescents, mainly from Sweden and Finland, receiving pandemic H1N1 influenza vaccine containing the adjuvant AS03 (Pandemrix) [158,159]. Since then, more cases of narcolepsy have been reported from children and adults receiving this vaccine containing AS03 adjuvant [160–162]. No increase in cases of narcolepsy has been reported from individuals receiving H1N1 vaccine without an adjuvant and with another oil-based adjuvant MF-59 [163]. While the relationship between the H1N1 vaccine containing AS03 and narcolepsy is being further evaluated, this shows the challenges in developing adjuvants and maintaining a balance between adjuvanticity and toxicity for vaccines used in masses. Narcolepsy has been associated with human leukocyte antigen (HLA) DQB1*06024 [164], with likely autoimmune link to this HLA, T-cell receptor polymorphisms [165], Tribbles 2 autoantibodies [166], and other environmental factors [158]. Adjuvants are used to modulate or enhance the immune response in an individual to the vaccine antigens. As discussed in this chapter, maintaining a balance between adjuvanticity and toxicity of the adjuvant is critical for prophylactic vaccines given to millions of healthy individuals.

## ACKNOWLEDGMENTS

I am thankful to Dr. James L. Kenney and Dr. Ramjay Vatsan for a careful review of the manuscript and valuable comments.

# Methods for Characterizing Proteins in Aluminum Adjuvant Formulations

MARTINUS A.H. CAPELLE, EMILIE POIRIER, and TUDOR ARVINTE

## 15.1 INTRODUCTION

Bovine serum albumin (BSA) mixed with aluminum hydroxide adjuvant (Alhydrogel) was used as a vaccine model for physicochemical studies. This chapter presents methods that allow studies of protein in vaccine formulations without separation of the protein from the aluminum salt adjuvant, including (1) UV-Vis transmission, (2) 90-degree light scatter, (3) fluorescence spectroscopy, (4) time-correlated single photon counting fluorescence lifetime, (5) light microscopy, (6) attenuated total reflection Fourier-transform infrared spectroscopy (ATR-FTIR), (7) UV resonance Raman spectroscopy, (8) sedimentation by gravitation, (9) analytical centrifugation with the LUMiSizer, (10) circular dichroism (CD), and (11) ultrasound resonator technology. Advantages of using fluorescence emission compared with UV-Vis absorbance for the determination of amount of protein bound to the adjuvant are discussed. The presented methods can be applied to characterize the vaccines' stability and improve the formulation. The physicochemical properties (e.g., conformation, binding strengths, type of aggregates or formed complexes) together with *in vivo* activity data will contribute to a better understanding of the mechanism(s) of action that can be applied to design more potent vaccines.

Few methods are described in literature to study the physical and chemical properties of vaccines consisting of a protein adsorbed onto an aluminum salt adjuvant. In this chapter, different methods are discussed for the characterization of BSA as a model protein after adsorption onto aluminum hydroxide adjuvant, Alhydrogel. The properties of BSA adsorbed onto the adjuvant are compared with BSA in water and to the adjuvant alone. Conformation and stability of proteins might change after adsorption onto aluminum adjuvants. The adjuvant properties,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

such as turbidity, morphology, compressibility, mass, and size, might also change after adsorption of a protein. The final vaccine obtained by mixing the antigen with the adjuvant will likely have different physical and chemical properties than the individual components before mixing.

Adjuvants are usually incorporated into vaccines to effectively stimulate and enhance the immune response. Aluminum adjuvants have been the most frequently used adjuvants in both human and veterinary vaccines for more than 60 years [1]. These adjuvants are generally recognized as safe, but despite their widespread use, their mechanism of action is still not completely understood. Aluminum-based adjuvants are low cost and have shown adjuvanticity with a variety of antigens [2]. The two mainly used aluminum adjuvants are Alhydrogel (aluminum hydroxide) and Adju-Phos (aluminum phosphate). Alhydrogel typically exists in a crystalline state and is mineralogically known as boehmite, which consists of corrugated sheets of octahedral aluminum [3,4]. Aluminum hydroxide particles are known to have a high surface area, about 500 $m^2/g$ [5], and needle-like or fibril morphology with a diameter of approximately 2 $nm^3$. In general, proteins adsorb better to oppositely charged adjuvants through electrostatic interactions [6]. Aluminum hydroxide has an excellent adsorptive capacity for many proteins because of the point of zero charge (PZC, analogous to the isoelectric point [IEP] of a protein) of approximately 11.

Bovine serum albumin adsorbed on Alhydrogel was used as a model protein vaccine for physicochemical studies. BSA adsorption on Alhydrogel is favored because of the electrostatic interaction between the negatively charged BSA (IEP of 4.7) and the positively charged nature of the aluminum hydroxide. Adsorption of negatively charged ovalbumin to negatively charged adjuvants has been observed, although the adsorptive capacity was greatest when the surface charge was positive [7]. Hem and coworkers proposed that structurally flexible proteins, such as ovalbumin, display more complex adsorption behavior than structurally rigid proteins, such as lysozyme, for which adsorptive behavior can be explained by electrostatic forces [7]. Other forces that contribute to the adsorption of proteins on aluminum adjuvants are hydrophobic, van der Waals, and hydrogen bonding [2].

Protein adsorbed to the adjuvant leads to more immunostimulation than unadsorbed protein [1]. Some of the described mechanisms involved in this process are the rendering of the protein multimeric, the delivery of multiple copies to the same cell. and the targeting of the immune system [8]. The main analytical studies performed on the final vaccine often consist of the determination of adsorption profiles and biological activity [1]; however, these biological assays are generally time consuming and of low accuracy and precision [9]. They also provide no direct information on the mechanisms of destabilization [9].

Chemical and physical stability studies can provide insight into the origin of the change responsible for vaccine inactivation. Within the academic and industrial communities, there is a need of high-resolution analytical methods that can detect small changes in complex macromolecular systems of multiple components, as was also stated by Middaugh and coworkers [9]. Previous studies from our group on

MMA383 antibody vaccine [10,11] and from another group on ricin A–chain vaccine [12] have highlighted the importance of formulation and characterization in regard to the immune response. Recently, several articles have appeared that report studies of the structure and stability of proteins after adsorption to aluminum adjuvants using calorimetry, fluorescence, electron microscopy, and infrared spectroscopy [10,11,13,14].

In this chapter, vaccine analyses were performed using the following spectroscopy and microscopy methods: (1) UV-Vis transmission, (2) 90-degree light scatter, (3) fluorescence spectroscopy, (4) time-correlated single photon counting fluorescence lifetime, (5) attenuated total reflection Fourier-transform infrared spectroscopy, and (6) light microscopy. In addition, new methods for characterizing protein adsorbed onto adjuvant vaccines are discussed: (1) UV resonance Raman spectroscopy, (2) CD, (3) ultrasound resonator technology, (4) sedimentation by gravitation, and (5) analytical centrifugation with the LUMiSizer. The majority of the developed methods are noninvasive and might also be applied for studying complex formulations such as virosomes, virus-like particles, nanoparticles, crystals, hydrogels, and other drug delivery systems. The methods were adapted with the aim of detecting small differences against a complex background and to be used for the characterization of vaccine formulations without dilution or protein desorption in conditions as near as possible to those used in medical applications [15].

## 15.2 ANALYTICAL METHODS

### 15.2.1 Sample Preparation

The samples were prepared by mixing 2% Alhydrogel with a BSA solution. The protein was added on top of the adjuvant. All measurements, except for the CD, were done on samples containing 3.4 mg/ml aluminum and 1.7 mg/ml BSA (0.5 mg/ml BSA per mg/ml aluminum). For the CD measurements, samples with a lower protein (0.1 mg/ml BSA) and adjuvant concentration (0.2% Alhydrogel) were used to avoid saturation of the detector. In both cases, no BSA was detected in the supernatant after centrifugation, indicating that all protein was either bound to the adjuvant or otherwise present within the pellet. This is expected as the protein concentration is below the adsorptive capacity of 2.2 mg BSA per milligram of aluminum of Alhydrogel in MOPS pH 7.4 [13]. The adsorptive capacity is defined as the maximum mass of protein adsorbed per milligram of aluminum.

### 15.2.2 UV-Vis Transmission

UV-Vis transmission spectra of BSA in water, BSA–Alhydrogel, and Alhydrogel are shown in Figure 15.1a. Measurements were performed with a Cintra 40 UV-Vis spectrometer (GBC Scientific, Dandenong, Australia) and in quartz cuvettes with 0.1-cm path length at 25°C. Adsorption of BSA onto the aluminum adjuvant resulted in a more turbid mixture (increased absorbance) and with a slope that is more parallel

**FIGURE 15.1** 1.7 mg/ml bovine serum albumin (BSA) in water (B), 1.7 mg/ml BSA with 0.6% Alhydrogel (A + B), 0.6% Alhydrogel (A) and water were analyzed by (a) UV-Vis absorbance spectroscopy, (b) 90-degree light scattering, (c) steady-state fluorescence emission (the wavelength with maximum emission intensities for BSA and BSA with Alhydrogel were 336 and 343 nm, respectively), and (d) steady-state fluorescence lifetime. The black decay is the light-scatter signal. (e and f) Light microscopy pictures of 0.6% Alhydrogel and BSA–Alhydrogel, respectively; the background square is 250 μm × 250 μm.

to the $x$-axis compared with the adjuvant without protein. The addition of protein to the adjuvant resulted in an increase in particle size, which resulted in a stronger Mie and Thompson scatter. A similar difference in scatter was also observed using the Tecan Safire plate reader (data not shown). In case of no interaction between the protein and adjuvant, the absorbance spectrum would be the sum of the two individual spectra. UV-Vis absorbance measurements in 96-well plates can be performed to determine the turbidity of vaccines similar to the high-throughput turbidimetry [16] and nephelometry [17] methods.

### 15.2.3 Ninety-Degree Light Scatter

Ninety-degree light-scatter measurements were performed with a Fluoromax spectrofluorometer (Spex Instruments S.A., Stanmore, UK). Hellma quartz cuvettes were used with a volume of 0.5 ml and a path length of $1.0 \times 0.2$ cm. The 90-degree light-scatter scan is a synchronous scan (i.e., the intensity was monitored at the same wavelength as the excitation light). The measurement range was nm to 750 nm with slits of 0.5 mm for the excitation and emission. Spectra were recorded with 0.01-s integration time per 1-nm increment. To avoid saturation of the detector, a neutral 90% absorbing density filter was placed in front of the detector.

Ninety-degree light-scatter intensity depends on the refractive index, particle size, and concentration. The BSA–Alhydrogel sample scattered significantly more light than the Alhydrogel sample without protein (Fig. 15.1b). The major contributor to the scatter signal is the adjuvant. Because the adjuvant concentration is the same, we can assume that the difference in scatter signal is caused by an increase in particle size after addition of protein to the adjuvant. In our experiments, we used 0.6% Alhydrogel, a relatively high adjuvant concentration. In such cases, to avoid saturation caused by strong scattering, the sample measurements can be performed at higher wavelengths and using short path length cuvettes. At lower adjuvant concentrations, the filter may not be needed. Also, at lower adjuvant concentrations of 0.3% Alhydrogel, we observed that the formulation can induce large differences in light-scatter properties of an antibody-Alhydrogel vaccine [10].

### 15.2.4 Fluorescence Spectroscopy

Steady-state fluorescence measurements were performed with a Fluoromax spectrofluorometer. The fluorescence intensities were measured at 25°C in a thermostated cuvette holder. Hellma quartz cuvettes were used with a volume of 0.5 ml and a path length of $1.0 \times 0.2$ cm: excitation was at 280 nm, and the emission was monitored between 300 and 450 nm. Spectra were recorded with a 0.1-s integration time per 1-nm increment and slits of 0.3 and 1.0 mm for excitation and emission, respectively.

The intrinsic tryptophan fluorescence intensity of BSA decreased and shifted to lower wavelengths after adsorption onto Alhydrogel. The maximum intensity for BSA in solution was at 343 nm and after adsorption onto Alhydrogel was 336 nm (Fig. 15.1c). This blue shift for BSA–Alhydrogel in relation to BSA in

solution is in concordance with the results of Jones et al. [13] and likely due to adsorption-induced conformational changes. The intensity of BSA in water is higher than in the presence of adjuvant, which is largely due to the turbidity of adjuvant containing samples; less fluorescence is recorded by the detector as a large portion is scattered and does not reach the detector. Because of the scatter issue, a comparison of protein adjuvanted vaccines should be mainly based on the position of the emission maximum.

Fluorescence lifetime of the tryptophan of BSA adsorbed on the aluminum adjuvant was measured with a time-correlated single-photon counting (TCSPC) IBH 5000U fluorescence lifetime spectrophotometer (IBH, Glasgow, UK). The samples were excited with a 279-nm NanoLED source. The spectrophotometer is equipped with a monochromator at the emission side. Optimum emission wavelength was determined to be at 345 nm. Data analysis was performed using the DAS6 software (IBH, Glasgow, UK). After reconvolution of the intensity decay with the instrument response function, the calculated data were analyzed by linear and nonlinear least-squares modeling. The mean weighted average lifetimes were calculated using the equation

$$\tau_F = \sum \alpha_i \tau_i^2 \Big/ \sum \alpha_i \tau_i \tag{1}$$

where $\tau_F$ is the fluorescence decay time and $\alpha$ is the normalized pre-exponential factor.

The mean weighted fluorescence lifetime of BSA in water (about 6.2 ns) is significant longer than the lifetimes of BSA–Alhydrogel (5.1 ns) (Table 15.1 and Fig. 15.1d). A difference of 0.9 ns is a large change in fluorescence lifetime; the experimental variation is around 0.05 ns. The blue shift of the intrinsic fluorescence and longer fluorescence lifetime of the BSA after adsorption on the adjuvant indicate that the protein is adsorbed in different conformations. The measurement of fluorescence in these turbid samples provides additional information on the local

**TABLE 15.1 Fluorescence and absorbance of BSA in water and BSA with Alhydrogel***

| | $A_{350}$ | $A_{350}\Delta$ | $I_{max}$ | $\lambda_{max}$ (nm) | $\tau_1$ (ns) | $\alpha_1$ (%) | $\tau_2$ (ns) | $\alpha_2$ (%) | $\tau_3$ (ns) | $\alpha_3$ (%) | $\tau_F$ (ns) |
|---|---|---|---|---|---|---|---|---|---|---|---|
| BSA in water | 0.039 | 0.00 | 1.6E + 08 | 343 | 0.7 | 0.8 | 3.5 | 20.7 | 6.6 | 78.5 | 6.2 |
| BSA with Alhydrogel | 2.57 | 0.38 | 7.1E + 07 | 336 | 1.1 | 6.6 | 2.8 | 36.1 | 5.9 | 57.3 | 5.1 |

*Fluorescence and absorbance data of the bovine serum albumin (BSA)–Alhydrogel and BSA solutions were compared. The UV-Vis absorbance at 350 nm ($A_{350}$) and the UV-Vis absorbance at 350 nm corrected with the absorbance of the adjuvant controls ($A_{350}\Delta$) are listed. The fluorescence emission maximum ($\lambda_{max}$) and the fluorescence intensity at emission maximum ($I_{max}$) were measured using quartz cuvettes and were derived from Figure 15.3. The best fit (X was between 0.9 and 1.1) to fluorescence lifetimes of the BSA formulations was obtained using three exponents; $\tau_1$, $\tau_2$, and $\tau_3$ are the decay times, and $\alpha_1$, $\alpha_2$, and $\alpha_3$ are the exponential factors.

environment of the tyrosine and tryptophan amino acids (e.g., aggregation, conformation, folding, or chemical degradation).

UV-Vis absorbance measurements are commonly performed to determine the antigen concentration in the supernatant. However, for vaccines with low antigen concentration, the UV-Vis absorbance is not sensitive enough for protein concentration determinations, and fluorescence measurements should be performed. The amount of protein bound to the adjuvant is calculated from the concentration in the supernatant after pelleting the aluminum adjuvant by centrifugation. A Tecan (Tecan Group Ltd., Männedorf, Switzerland) Safire 2 microplate reader was used to determine intrinsic fluorescence emission of BSA remaining in the supernatant after centrifugation. Fluorescence emission was measured from the bottom after excitation at 280 nm using bandwidths of 5 nm for both excitation and emission. The fact that fluorescence is more sensitive in protein detection is documented by the following experiment. Three samples consisting of 0.3 mg/ml BSA with 0.025%, 0.03%, and 0.3% Alhydrogel were centrifuged, and the supernatant was measured by UV-Vis absorbance and fluorescence emission in a 96-well plate (Fig. 15.2). No BSA was found in the supernatant of the sample with 0.3% Alhydrogel by both methods. However, the fluorescence emission of the supernatant of BSA with 0.03% Alhydrogel showed a clear fluorescence spectrum, but nothing was detected by UV-Vis absorbance spectroscopy; the fluorescence intensity corresponded to 1% of the initial 0.3 mg/ml BSA (99% bound). For the BSA 0.025% Alhydrogel samples the UV-Vis and fluorescence methods gave values for bound BSA of 84% and 87%, respectively. The fluorescence emission method was more sensitive, easier to reproduce, and less influenced by the scatter of "left-over" adjuvant in the supernatant. Fluorescence spectroscopy is, in our experience, the method of choice for determination of antigen concentration in supernatants.

### 15.2.5 Light Microscopy

Light microscopy observations were performed with a 10× objective on a Leica DM RXE microscope (Leica Microsystems GmbH, Wetzlar, Germany) equipped with a mercury lamp. The images were acquired with a Camera Ecoline Digital and processed using the Cyberlink Power Director software (Cyberlink, Vaals, Netherlands) operating under Windows 7. Microscopy slides with a fixed distance of 0.1 mm between the slide and the cover glass were used. The size of the 4 × 4 grids is 1 mm × 1 mm and corresponds to a volume of 0.1 μl. BSA induced changes in the morphology of the complexes between protein and adjuvant; in the presence of protein, the aluminum structures appear more cloudy and turbid (Fig. 15.1e and f). These induced changes in morphology are immediate and are in agreement with the spectroscopic and light-scatter results.

### 15.2.6 Attenuated Total Reflection–Fourier Transform Infrared Spectroscopy FTIR

The secondary structure of BSA adsorbed on Alhydrogel was characterized using an IdentifyIR (Smiths Detection, Danbury CT, USA) ATR-FTIR spectrometer. Samples

**FIGURE 15.2** Fluorescence emission (a) and UV-Vis absorbance (b) of the supernatant of 0.3 mg/ml bovine serum albumin (BSA) with 0.025% Alhydrogel, 0.03% Alhydrogel, and 0.3% Alhydrogel, as indicated in the figures.

were measured directly in the intact vaccine formulation without any form of sample treatment. The IdentifyIR contained a three reflections diamond-attenuated total reflection (ATR) crystal. In ATR-FTIR, the absorption is measured of the evanescent wave that penetrates the solution when the incident light is reflected at the crystal–liquid interface [18]. The ATR crystal was covered completely with BSA–adjuvant suspension and imaged with the light microscope accessory with a 100x magnification. Data collection were between 4000 and 650 $cm^{-1}$ with a 4–wave number resolution. The average of 256 scans was used. The acquired ATR-FTIR spectra were corrected for absorption of water.

ATR-FTIR spectra showed that the secondary structure of BSA changed after adsorption to Alhydrogel (Fig. 15.3a). The absorption bands that were attributed to the adjuvants structure are between 3000 and 3600 $cm^{-1}$ and around 1100 $cm^{-1}$. The strong shoulder observed in the Alhydrogel samples at 3100 $cm^{-1}$ and the peaks at 3300 and 1100 $cm^{-1}$ are characteristic of aluminum hydroxide and indicates the existence of structural hydroxyl environments [3]. The BSA–Alhydrogel sample had distinct peaks at wave numbers of 2750 to 3000 $cm^{-1}$, which was ascribed to protein-inflicted changes in the structural hydroxyl environments of Alhydrogel and not protein characteristic peaks. No peaks were determined for the BSA in water sample because of the low protein concentration (data not shown); a concentration of about 10 mg/ml BSA is required to obtain a proper ATR-FTIR spectrum. Because the BSA in presence of the adjuvant is no longer in solution as it is adsorbed onto the suspended aluminum particles, the ATR-FTIR intensities are stronger. Therefore, ATR-FTIR spectroscopy measures mainly the adsorbed antigen and less the solubilized antigen.

Amide I (1650 $cm^{-1}$) and amide II (1520 $cm^{-1}$) absorption bands are characteristic for the peptide bonds in proteins. The amide I band for BSA–Alhydrogel is typical for α-helix, and amide II band at 1520 $cm^{-1}$ was assigned to β-sheet [19]. BSA–Alhydrogel had similar intensities for both bands, as was previously reported [13], which can be attributed to presence of both α-helices and β-sheet.

ATR-FTIR spectroscopy for secondary structure analysis of different proteins adsorbed onto adjuvant has been described [13,19–21]. The sample handling, such as loading and cleaning of the crystal, is rapid and simple. Measurements are highly reproducible because of the constant "optical path" that depends on the crystal and solution refractive indices [18,22]. A few crystals or volumes of around 10 μl are sufficient to cover the surface of the crystal. With the IdentifyIR, the crystal surface was continuously monitored by an integrated light microscope and shown on a LCD screen.

### 15.2.7 Ultraviolet Raman Spectroscopy

Ultraviolet resonance Raman spectroscopy with a high-throughput sample setup at the Central Laser Facility of the Rutherford Appleton Laboratory, UK, was used [23,24]. Raman spectra were recorded using a 244-nm laser excitation generated by frequency doubling an Innova FRED 300c Ar+ laser; the experimental conditions were similar to those described by Patois et al. [23]. The Raman spectrum of BSA

**FIGURE 15.3** 0.6% Alhydrogel (A, gray) and 1.7 mg/ml bovine serum albumin (BSA) with 0.6% Alhydrogel (B, black) were analyzed by (a) ATR-FTIR (attenuated total reflection–Fourier transform infrared) absorbance spectra, BSA–Alhydrogel had distinct amide absorption bands and no absorbance was detected for Alhydrogel around the amide I and II bands; (b) ultraviolet Raman spectroscopy, BSA–Alhydrogel corrected for Alhydrogel (C); and BSA–Alhydrogel corrected for BSA (D).

was obtained after subtracting the adjuvant signal from the BSA–Alhydrogel sample (Fig. 15.3b). In Figure 15.3b, the spectra are presented with an offset and not overlaid as is custom for UV resonance Raman spectroscopy. Interestingly, this BSA spectrum from the BSA–Alhydrogel sample was similar to the Raman spectrum of BSA in water, showing that the overall structure of BSA remained unchanged; the average of the structure of BSA in solution as well as BSA adsorbed onto the adjuvant. These data show that UV resonance Raman spectroscopy is a suitable technique for the investigation of proteins bound to vaccine adjuvants. For identification of the various Raman peaks, refer to our recent publication on Raman spectroscopy [23].

### 15.2.8 Sedimentation by Gravitation

Aluminum salt adjuvants consist of particles in suspensions that can sediment in time. The sedimentation by gravitation can be documented by (1) measurement of 90-degree light scatter [10] or turbidity in time and (2) photographic measurement of the pellet height in time. The first method was applied for an antibody vaccine with Alhydrogel adjuvant in which we reported the measurements of gravitational sedimentation of large particles using 90-degree light scatter [10]. At the same concentration of antibody and adjuvants, different sedimentation properties were observed [10]. The results showed that sedimentation behavior of protein aluminum adjuvant vaccines is influenced by different factors, such as the particle mass, viscosity, density, and buoyancy.

An alternative method to characterize the sedimentation kinetics is the photographic measurement of the pellet height in time. In the present study, the BSA–Alhydrogel vaccines in 1-ml syringes and 3-ml cuvettes were photographed at different time intervals (data not shown) against a black background to record the sedimentation process. Sedimentation equilibrium was observed after 2 weeks at room temperature. Advantages of using syringes include the measurement in small volumes using standard and low-cost laboratory consumables, good control of pellet height, and the possibility to measure noninvasively in prefilled syringes. In the case that the sedimentation is fast (within minutes), the cuvette measurements using 90-degree light scatter provide a more accurate method to study sedimentation kinetics [10].

### 15.2.9 Sedimentation Analysis Using Analytical Centrifugation

Accelerated sedimentation analysis on the BSA adjuvant samples was performed using an analytical centrifuge LUMiSizer 610 (L.U.M. GmbH, Berlin, Germany). The LUMiSizer 610 measured the intensity of the transmitted near infrared (NIR) light as function of time and position over the full sample length. The centrifugal force applied was $146 \times g$. NIR transmission profiles were recorded with an interval of 10 s during 40 min of separation at a thermostated temperature of 20°C. Data were analyzed using the LUMiSizer software SEPView (L.U.M. GmbH) as a function of the position inside the sample as a distance from the center of rotation. The

progression of the transmission profiles contains information on stability and on the kinetics of the sedimentation processes. Transmission profiles are representative of the variation of particle concentration inside the sample (low transmission means high particle concentration; high transmission means low particle concentration).

Sedimentation analysis with the LUMiSizer 610, using centrifugal force and detection in the NIR, can distinguish between BSA–Alhydrogel and Alhydrogel without protein. This analytical centrifugation method is fast (20–40 min) and permits the determination of sedimentation profiles of up to 12 different samples simultaneously [25,26]. The evolution of transmission profiles in time for BSA–Alhydrogel is shown in Figure 15.4a. The separation process was characterized by a sharp sedimentation-front moving toward the bottom of the cell. The decreasing spacing between consecutive profiles of BSA–Alhydrogel (Fig. 15.4a) can be explained by the consolidation of a closed three-dimensional network formed in case of flocculated particles. The resistance against compaction increases as sedimentation proceeds because of increased interactions between the higher formed local concentration of particles. Near the cell bottom, a compact sediment was formed (corresponding to the lowest transmission). The length of the sediment or pellet height and the volume or the filling height are measured directly with the LUMiSizer (Fig. 15.4a). As the sample is centrifuged, it becomes increasingly more clear, and the turbid sediment front moves to the right. The change in time of the distance from the top of the cuvette to the turbid sediment front for a given transmission value, (e.g., at 60% transmission in our case) is called the front-track curve (Fig. 15.4b). The slope in each point (first derivative) of the front-tracking curve defines the sedimentation velocity at that time point. The initial sedimentation velocities (velocity $= \Delta$ Position/$\Delta$ Time) during the first minute for BSA–Alhydrogel and Alhydrogel are 10 and 3 mm/min, respectively (see Fig. 15.4b). In our case, after 30 min, the position of the front no longer changed significantly, and the pellet percentage of total volume was calculated. Figure 15.4b shows that the adjuvant with BSA sediments faster and forms a larger pellet than the adjuvant alone. The mass of the formed BSA–adjuvant complexes is larger than those without the protein, resulting in an increased sedimentation rate. The size of the pellet is not directly correlated to the mass of the particles and depends more on the particle morphology, charges, and colloidal properties. In this case, the larger pellet might be formed because of interactions (e.g., repulsions) between the BSA–adjuvant particles.

These measurements permit a good characterization of vaccines by all of these parameters—the tracking curves pattern, the sedimentation velocities, and the pellet height as a percentage of total volume. Thus, the LUMiSizer provides information on colloidal properties and particle size of turbid vaccines, and it may be also be a useful method for the characterization of other vaccine adjuvants such as microparticles [8,27].

### 15.2.10 Circular Dichroism

Circular dichroism spectra were obtained with a Jasco J-815 spectropolarimeter (Tokyo, Japan) equipped with a thermostated cell holder. Measured samples were

**FIGURE 15.4** LUMiSizer experiments. (a) The changes in time of transmission profiles for 1.7 mg/ml bovine serum albumin (BSA) adsorbed on 0.6% Alhydrogel analyzed during centrifugation at 146 × *g* forces. The separation process is characterized by a sharp sedimentation front moving toward the bottom of the cell. The sharp dip in the transmission profiles at about 103 mm is due to the liquid–air interface and represents the filling height of the sample. The position of the cell bottom is at about 130 mm. The LUMiSizer cuvette is drawn on the top (a) and on the side (b) of the figures. (b) Front-track sedimentation curves by tracking the sedimentation front at 60% transmission value. BSA–Alhydrogel (dark gray) had a faster sedimentation compared with Alhydrogel (black). BSA–Alhydrogel and Alhydrogel had initial sedimentation velocities (slope) of approximately 10 and 3 mm/min and pellet heights of 6 and 5 mm, respectively.

(1) 0.1 mg/ml BSA in water, (2) 0.1 mg/ml BSA with 0.2% Alhydrogel (corresponds to 1 mg/ml aluminum), and (3) 0.2% Alhydrogel. Far-UV spectra were measured between 190 and 260 nm in quartz cuvettes with 0.1-mm path length. Spectra were recorded at a speed of 5 nm/min, with a step size of 0.2 nm, a response time of 16 s, and a spectral bandwidth of 1 nm. An average of three scans was recorded.

To study the thermal stability of the vaccines, the ellipticity at 220 nm of the protein and protein adsorbed onto adjuvant were measured between 20 and 90°C in a cuvette with 0.1-cm path length. The thermal stability method is described in detail in a recent publication from our group [28]. The kinetic melting of the protein was recorded with a scan speed of 60°C/h, response time of 4 s, bandwidth of 1 nm, and data pitch of 0.1°C.

Circular dichroism measurements showed that whereas the thermally induced unfolding of BSA in water was 69.7°C, for the BSA–Alhydrogel, the unfolding temperature was 72.3°C (Fig. 15.5). This shows that the BSA conformation is protected against thermal unfolding by interactions with aluminum adjuvant. To our knowledge, this is the first publication describing the use of CD to determine the thermal stability of protein–adjuvant vaccines without prior sample treatment. In the present CD study, a concentration of 0.2% Alhydrogel was used, and measurements were performed in a cuvette with a path length of 0.1 mm. Smaller path length CD cuvettes could be used if the sample is more turbid. Turbidity limits the use of CD for protein-adjuvant vaccines. However, the aim is often to use a low adjuvant concentration (e.g., 0.1%), and CD could add complementary information regarding the stability and conformation of the adsorbed antigen.

### 15.2.11 Ultrasound Resonator Technology

Ultrasonic resonator technology (URT) measurements were carried out by the ResoScan system from TF instruments (TF instruments GmbH, Heidelberg, Germany). The ResoScan instrument has two measurement cells with each a path length of 7 mm, which act as ultrasonic resonators. Cells were filled with a volume of 200 μl and closed to prevent evaporation. The samples were measured in one cell with in the reference cell water or 0.6% Alhydrogel for BSA in water and BSA–Alhydrogel, respectively. An optimal resonance peak (master peak) at 7.8 MHz was used for the ultrasound velocity measurements. Before the start of the thermal scans, the samples were kept for 5 min at 20°C. The difference in ultrasound velocity ($\Delta U$ in m/s) between the sample and its reference was recorded between 20 and 85°C, temperature increase rate of 300 mK/min. Data were reprocessed by the UltraView 3.2 software (TF Instruments GmbH).

Ultrasound resonator technology (URT) measures the sound velocity in solutions, which is mainly influenced by the hydration shell of the solute molecules. The sound velocity is influenced by protein solutions properties such as protein size, conformation, and aggregation as well as by the other constituents (e.g., sugars, salts, buffer). Measurement of the ultrasound can be used for very turbid protein samples, protein–adjuvant vaccines, emulsion, and creams [29,30].

Figure 15.6 presents the temperature dependence of ultrasound velocities of BSA in water and BSA–Alhydrogel. The ultrasound velocity in BSA–water sample decreased steadily between 20 and 85°C. The sound velocity in the BSA–Alhydrogel sample was different; it decreased between 20 and 30°C and increased between 35 and 70°C. These changes are likely due to the strong effect of BSA on the structure and morphology of aluminum (Fig. 15.1e and f). Thus, URT measurements

**FIGURE 15.5** (a) Circular dichroism spectra of 0.1 mg/ml bovine serum albumin (BSA) and 0.1 mg/ml BSA with 0.2% Alhydrogel. Thermal stability of (b) BSA–Alhydrogel and (c) BSA in water. The melting temperature was determined after fitting with a two-term van't Hoff equation as described by our group in an earlier publication [28].

**FIGURE 15.6** Ultrasound resonance measurements: 1.7 mg/ml BSA in water, and 1.7 mg/ml BSA with 0.6% Alhydrogel after subtraction of the corresponding background.

bring new information for the comparison of different vaccine formulations and stability studies complementary to CD analysis.

## 15.3 CONCLUSION

In the early development phase of a new vaccine, many analytical methods are required to study its chemical and physical stability. This chapter has discussed different methods for the characterization of the vaccine model BSA–Alhydrogel. It was shown that BSA changed conformations after adsorption on Alhydrogel and was more stable toward thermal conformation changes. BSA strongly interacted with the aluminum hydroxide particles, resulting in more turbid suspensions that sedimented much faster than Alhydrogel suspensions. Many of the analytical methods can be adapted to 96-well plates or to small volumes. The noninvasive methods permit the characterization of protein vaccines in conditions as near as possible to the one used in therapeutic applications and open possibilities for new approaches for a faster development of stable and active protein vaccines.

## ACKNOWLEDGMENTS

The authors wish to thank Filippo Mulinacci for his help with the CD experiments and Dr. Steven Bell and Dr. Iain Larmour from Queen's University Belfast for their

help with performing the UV Raman analyses. The authors acknowledge the experimental time granted by the UV Raman facilities at the Central Laser Facility of the Rutherford Appleton Laboratory, UK, and the local technical assistance from Sue Tavender.

# The State of the Art and Future of Gene Medicines

FRANK JACOBS, STEPHANIE C. GORDTS, and BART DE GEEST

## 16.1 INTRODUCTION AND HISTORIC PERSPECTIVE

Genetic diseases are a major source of hospitalizations and mortality worldwide [1]. Although there has been a stark improvement in diagnostic methods for detecting the underlying genetic defects over the past decades, the development of novel therapeutics has been lagging. Gene therapy holds great promise as a cure for these disorders. However, the application of gene therapy is not restricted to the treatment of inherited diseases such as severe combined immune deficiency, familial hypercholesterolemia, cystic fibrosis, and hemophilia but also involves the treatment of a broad spectrum of disorders such as cancer, Parkinson's and Alzheimer's disease, arthritis, diabetes, and cardiovascular diseases.

This chapter discusses the significant technological progress that has been made in the development of gene therapy strategies and the application of these strategies in specific therapeutic niches. More specifically, the chapter aims to provide an overview of selected highlights from the past (preclinical development), current (first-in-human [FIH] clinical trials), and future (remaining hurdles and regulatory aspects) of different gene therapy approaches. In these discussions, the chapter focuses on gene therapy approaches using viral vectors because they are generally considered to be more efficacious and have yielded the most prominent clinical successes. As such, an in-depth discussion of gene therapy strategies that are based on nonviral vector systems is not included in this chapter, and readers are referred to excellent reviews covering this aspect of the gene therapy field [2–4].

The term "gene therapy" was first coined in the 1960s and was based on novel contemporary insights into the genetic code. This is clearly illustrated in the 1963 assay by Joshua Lederberg in which he stated: "The ultimate application of

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

molecular biology would be the direct control of nucleotide sequences in human chromosomes, coupled with recognition, selection, and integration of the desired genes" [5]. The idea of using modified viruses to carry this genetic load and transport into the affected cells came not much later in 1966, when Edward Tatum postulated that "Finally we can anticipate that viruses will be used effectively for man's benefit, in theoretical studies concerning somatic cell genetics and possibly in genetic therapy" [6,7]. In 1967, Nobel Laureate Marshall Nirenberg wrote in *Science* about the possibility of reprogramming cells to produce "synthetic" messages and warned that society may not be ready to cope with this new human power over genetics [8]. However, the idea of gene therapy remained largely theoretical, and significant progress was hampered by various technological and ethical restrictions. The long and winding road that has since been traveled from this first notion of gene therapy has recently been elegantly reviewed [9–11].

In the 1970s, the onset of new technologies, such as restriction endonucleases, polymerase chain reaction (PCR), and sequencing techniques, finally allowed researchers to translate the elusive idea of gene therapy into practice. Initial *in vitro* studies showed that it was indeed possible to transfer DNA into cells and correct an underlying genetic defect [12]. However, the transfer of naked DNA was tedious, and the efficiency was low, underscoring the need for more efficient gene delivery systems. The following decades saw the development of different viral vector systems, including retroviral vectors [13], adenoviral vectors [14], and adeno-associated viral (AAV) vectors [15]. Using these novel technologies, various groups showed efficient correction of genetic disorders in animal models. An in-depth discussion of the preclinical development of these vector systems falls outside of the scope of this chapter and has been extensively reviewed elsewhere [16–18].

Although it was beyond any doubt that gene therapy had great potential, the field had been hyped, and progress was hampered by the rush for quick application studies and clinical trials. Unfortunately, this hype resulted in a lack of studies aimed at evaluating basic vectorology, innate and adaptive immune responses, vector biology, vector targeting, and basic mechanistic aspects of gene therapy approaches. The tragic death in October 1999 of Jesse Gelsinger, who was treated with an adenoviral vector for the treatment of a urea cycle disorder [19], indicated again that the field required more time to mature scientifically before significant therapeutic advances could be expected.

Since then, continuous refinement of viral vector systems, in combination with an increased understanding of the underlying vector biology and host immunology, has led to successful development of clinically viable gene therapy strategies. As will be discussed in the following paragraphs, the gene therapy field has yet again reached an important crossroad. Whereas the efficacy and safety of last-generation viral vectors has been scrutinized in various animal models, the question now remains how these results can be extrapolated to humans. Therefore, data from a new generation of FIH clinical trials are urgently needed to assess the current status of the gene therapy field and to identify the remaining challenges for ensuring clinical efficacy.

## 16.2 GENE THERAPY IN THE CLINIC

As briefly alluded to in the introduction, significant efforts have been made over the past decades to assess the potency of different gene transfer systems to correct numerous diseases in preclinical animal models. These consorted efforts have led to the successful translation of several gene therapy approaches into the clinic (Fig. 16.1). Indeed, some of the most promising results have only been obtained in the past few years [1,20,21]. In the following paragraphs, we will discuss the most salient examples of successful gene therapy trials. Interestingly, the development of gene transfer strategies for these highly diverse diseases has been intensely interconnected. With regard to technological aspects, the generation, development, and characterization of different vector platforms have been a collaborative effort by many investigators across the world. On the other hand, relevant clinical data in the field have always been scarce, and therefore the willingness to openly share and discuss preliminary data has been an important factor in ensuring efficient optimization of clinical protocols (see below). As such, it is clear that although the following paragraphs will highlight some of the most encouraging and notable studies, many other groups have also contributed heavily, albeit indirectly, to the further development of these gene transfer strategies.

### 16.2.1 Gene Therapy for Severe Combined Immunodeficiencies

One of the most fitting examples of the mercurial history of the gene therapy field is the development of a therapy for patients with severe combined immunodeficiency (SCID). The only currently available treatment for SCID is allogeneic hematopoietic stem cell transplantation. However, this technique is associated with inherent

**FIGURE 16.1** Clinical gene therapy strategies: an overview of selected target organs and diseases that are currently pursued in clinical gene therapy trials.

complications and is known to possibly result in graft-versus-host disease. These limitations are even more pronounced in patients without suitable human leukocyte antigen (HLA)–matched donors. The general lack of therapeutic options for patients with SCID, together with the life-threatening complications of the disease, have identified SCID as a prime candidate for gene therapy. To date, gene therapy approaches have focused on the two most common forms of SCID: *adenosine deaminase* SCID (ADA-SCID) and *X-linked* SCID (SCID-X1).

ADA-SCID is the second most common cause of SCID (10–20% of all SCID patients) and is caused by a defect in the enzyme adenosine deaminase (ADA), which is required for the breakdown of purines. As a result of this defect, the conversion of ribonucleotides to deoxyribonucleotides is disturbed, leading to abnormalities in B-cell, T-cell, and natural killer (NK) lymphocyte development and function. Without treatment, ADA-SCID is generally fatal within the first year of life, underscoring the necessity for early interventions [22]. A unique feature for ADA-SCID is that, in addition to allogeneic hematopoietic stem cell transplantation, patients also respond to enzyme replacement therapy (ERT) with modified ADA-enzyme. However, because response to ERT is highly variable, the long-term prognosis on ERT is poor [22]. Initial gene therapy trials for ADA-SCID performed in the early 1990s focused on *ex vivo* transduction of lymphocytes [23,24] and hematopoietic progenitor cells [25] in patients who were receiving ERT. Although the procedure was shown to be safe, patients did not show any signs of efficacy, which was later attributed to the low levels of engraftment of genetically corrected cells and a poor selective advantage of these cells because of the maintenance of the ERT [26]. Additional studies have since then identified a more efficient gene transfer protocol using $CD34^+$ bone marrow cells combined with the administration of a nonmyeloablative dose of chemotherapy before cell infusion [27]. Based on these novel insights, three additional trials have recently been performed in Italy, the United Kingdom, and the United states. These studies included a combined total of 30 patients, and patients have now been followed for up to 10 years without any evidence of leukemic transformations [21,28]. Results have been encouraging, and most patients displayed progressive immune reconstitution, efficient systemic detoxification, and long-term multilineage engraftment. Moreover, 21 of 30 patients (i.e., 67%) who have been treated were able to stop ERT completely, indicating that the metabolic and immunologic correction in these patients has been achieved solely by the gene transfer vector infusion. Based on these positive results, Gaspar et al. [21] postulated that, given the high level of safety and efficacy, gene therapy could be considered as the first treatment option in the absence of suitable HLA-matched bone marrow donors, especially because failure of gene therapy does not preclude the patients from further treatment options such as ERT or bone marrow transplantation.

SCID-X1 is caused by mutations in the gene encoding the interleukin-2 receptor $\gamma$ chain (IL2RG), and this is the most common cause of SCID (accounting for 40–50% of all SCID patients) [20]. Patients display a complete absence of functional T cells and NK cells, and the function of B cells is severely impaired. SCID-X1 is a particularly attractive target for gene therapy because of the profound growth and survival advantage of genetically corrected cells. To date, two trials totaling

20 patients have been performed by Hacein-Bey-Abina et al. [29,30] and Gaspar et al. [20]. The technology that was used in these studies is essentially the same as was used for the trials for ADA-SCID [21,28]. Although there were some notable differences in the study design of the two SCID-X1 trials (including vector design, vector envelope protein composition, and *in vitro* transduction conditions), the combined results of these studies indicate some clear converging results [31]. First, the survival of gene transfer recipients compared favorably with recipients who had received mismatched allogeneic bone marrow transplants. Seventeen patients (85%) showed sustained presence of transduced T lymphocytes. Interestingly, the kinetics of T-cell recovery after gene transfer in SCID-X1 was markedly faster than what was observed in the setting of ADA-SCID. This may be caused by remaining purine toxicity in the thymic epithelium or peripheral tissues in the context of ADA-SCID. Alternatively, repopulation of T cells in SCID-X1 may be artificially accelerated by the accumulation of T-cell precursors because of their blocked differentiation from the stem cell pool. Second, whereas T-cell counts have been shown to be stable over time, long-term persistence of NK cells and B cells has been less impressive. Nevertheless, patients have been shown able to fight off infections without additional pharmacotherapy and approximately half of the patients do not require any immunoglobulin substitution [32].

However, these promising results have been severely marred by the development of a hitherto unforeseen complication: the development of T-cell acute lymphoblastic leukemia (T-ALL) because of insertional oncogenesis caused by the gammaretroviral vector. In total, five patients across both studies developed T-cell leukemia within 2 to 5.5 years after gene transfer, and this has since led to the discontinuation of these trials [32]. After chemotherapy, one patient succumbed from refractory leukemia, but the remaining four patients recovered and showed sustained T-cell immunity. Extensive studies have since shown that in all cases, the underlying cause was integration of the provirus into a proto-oncogene locus (predominantly into the *LIM domain only 2 [LMO2]* locus). These studies further highlighted that retroviruses preferably integrated into genes, especially genes that are actively transcribed. It quickly became clear that the viral *late terminal repeats* (LTRs) displayed an enhancer activity that could turn on transcription of the target gene and could thus trigger the leukemic progress [33]. Interestingly, none of the patients from the ADA-SCID trials developed leukemia, although the vectors used in these studies were highly similar. This strongly suggests that one or more disease-related factors influence retroviral integration. Whereas the underlying mechanisms for these differences remain highly speculative [26], these observations underscore the need for developing alternative vector systems.

Taken together, the hard-learned lesson of two decades of gene therapy for SCID is one of cautionary optimism. In the absence of HLA-matched bone marrow donors, gene therapy has been shown to be a viable, safe, and efficacious treatment option. However, the observations of an increased risk for leukemia have highlighted the inherent complications of the first generation of retroviral vectors. Lessons from these studies have led to the design of improved vectors that are less likely to transactivate proto-oncogenes by including internal promoters to drive transgene

expression or, alternatively, the inclusion of insulating DNA sequences that shield the surrounding genomic DNA from the enhancer effects of the LTRs [34]. Given the genotoxic risk associated with gammaretroviral vectors, future trials for SCID, as well as other immunodeficiencies, will be performed using self-inactivating lentiviral or gammaretroviral vectors devoid of viral regulatory elements [35,36]. Trials evaluating the safety and efficacy of these vectors have been initiated, and their results are eagerly awaited. On the basis of the seminal observations with SCID, a broad array of other blood cell diseases are being approached with gene therapy, including Wiskott-Aldrich syndrome, chronic granulomatous disease, X-adrenoleukodystrophy, metachromatic leukodystrophy, Hurler's syndrome, and β-thalassemia.

### 16.2.2 Hemophilia B

Hemophilia B is an X-linked recessive bleeding disorder. The disease is caused by mutations in the gene encoding the blood coagulation factor IX (FIX), a serine protease that is essential for formation of the fibrin clot. Spontaneous bleeds into joints and soft tissues of inadequately treated patients with severe hemophilia B (i.e., patients with $<1\%$ remaining FIX activity) lead to chronic debilitating arthropathies. In addition, spontaneous bleeds in the brain can result in severe neurologic complications and death. Extensive studies on the natural history of hemophilia B have indicated that raising the circulating levels of FIX into the range of a few percent of normal suffices to greatly improve the symptoms of the disease. The current mainstay therapy for hemophilia B is infusion of recombinant or plasma-derived FIX protein. However, protein infusion therapy is not always efficient, and the relatively short half-life of FIX requires frequent readministrations (two to three times a week). The average cost of protein therapy has been estimated to be more than $300,000 per year for an adult patient who receives prophylactic treatment, resulting in a lifetime treatment cost of more than $20,000,000 [1,37]. Additional features that have attracted interest in hemophilia as a target for gene transfer include (1) a wide therapeutic window (levels up to 150% are still within the normal range), (2) standardized endpoint assays, (3) FIX can be expressed from liver as well as extrahepatic tissues such as muscle, and (4) the availability of both small and large animal models.

Initial studies focused on the muscle as a target organ because myocytes had previously been shown to be able to maintain long-term transgene expression of reporter genes after direct intramuscular (IM) delivery of AAV vectors. In addition, at that time, IM injections were regarded as a more conservative and safe initial approach with reduced risks for the patients [38]. Animal studies in mice and dogs later confirmed the possibility of generating long-term FIX expression in the absence of serious adverse effects after IM injection [39,40]. Based on these results, the first phase I clinical trial for IM delivery of AAV2 in patients with severe hemophilia caused by missense mutations was initiated in 1999. Consequently, this was also the first clinical trial evaluating AAV gene transfer to the muscle. Initial results indicated that although parenteral vector administration was not associated with toxicity at any dose tested, circulating FIX levels were subtherapeutic (i.e., $\leq 1\%$ of normal)

[41–43]. In addition, the large number of injections required to transduce adequate amounts of skeletal muscle precluded injection of the predicted therapeutic dose in humans. *Post-hoc* analysis indicated no inhibitor formation against the expressed FIX protein in the muscle, and FIX could be detected for several years via immunohistochemistry performed on muscle biopsies. However, attempts to further improve gene transfer efficiency to the muscle in dog models indicated that depending on the context, inhibitory anti-FIX antibodies could indeed be generated after IM injections, precluding further development of this strategy [44]. Based on these findings, it was postulated that changing the target organ to liver could substantially increase the therapeutic index of AAV gene transfer vectors for hemophilia B. Indeed, previous studies in mice, dogs, and nonhuman primates (NHPs) had indicated that there was a strong dose-advantage in favor of liver, in the order of 10- to 100-fold, which was likely attributable to the higher secretion efficiency of hepatocytes into the circulation [45,46]. In addition, gene delivery to the liver also appeared to promote tolerance to the transgene product [47].

Based on the results of preclinical studies in animal models, the first clinical trial for liver-directed gene transfer was initiated in 2001 [48]. In this open-label, dose-escalation study, a recombinant AAV2 vector encoding human FIX was delivered through the hepatic artery in humans with severe hemophilia B. This was also the first clinical study in which AAV vectors were administered into the circulation. Taking into account that a previous trial evaluating systemic gene transfer with an adenoviral vector resulted in a fatal complication in one of the enrolled patients [19], the regulatory agencies therefore (understandably) required this trial to start at doses that were several-fold lower than the therapeutic dose that had been predicted based on data from animal studies. As could be expected, none of the subjects enrolled in the lower two dose cohorts presented any evidence of vector-related toxicity, and no measurable FIX activity could be determined. However, one subject in the highest dose cohort showed a therapeutic increase in FIX activity of up to 10–12% of normal levels (up from $<1\%$ at baseline). In contrast to long-lasting expression in hemophilic dogs and NHPs using similar vectors, expression at therapeutic levels in this subject was short lived. Starting at 5 weeks after vector administration, FIX expression began to fall and gradually declined to baseline at 10 weeks after vector infusion. The gradual decline in FIX levels coincided with an asymptomatic rise in serum transaminase levels between 4 and 8 weeks after vector administration. Antibodies directed against the FIX transgene could not be detected, and possible toxic or infectious causes for the increase in liver enzymes were excluded. A second subject receiving an identical dose of the AAV2 vector did not show any signs of FIX expression or liver toxicity, which was attributed to impaired transduction efficiency caused by higher levels of pretreatment AAV2 neutralizing antibodies in this patient (see below). Finally, one additional subject who was dosed at a fivefold lower dose also displayed a self-limited rise in liver enzymes with similar kinetics. Because none of the human subjects in these studies displayed a *null* mutation of FIX and because both antibody and T-cell responses directed against FIX were absent, studies focused on cellular immune responses directed toward the AAV capsid. A series of follow-up experiments suggested that T cell–mediated immunity to AAV capsid antigens

caused destruction of AAV2-transduced hepatocytes [48]. A strong correlation was shown between the time course of $CD8^+$ T cells responses to capsid, the observed transient increase in liver enzymes, and the loss of transgene expression [49]. Nevertheless, this association does not prove causality. Further studies evaluating the underlying mechanism are currently ongoing.

With regard to further clinical trials, the question remains whether it is possible to avoid the occurrence of an immune response against the vector even with an incomplete understanding of the mechanisms that may drive cellular immunity. Strategies that are currently under evaluation include the combination of immunosuppressive drugs in order to block activation and proliferation of the capsid-specific T cells until the capsid has been degraded and cleared from the transduced hepatocytes (Ragni et al., NTC00515710). Alternatively, Nathwani et al. [50] developed a novel AAV vector that was optimized in order to reduce the vector dose required to achieve therapeutic FIX expression, thus possibly reducing activation of the immune system. First, the authors chose to use an alternative AAV serotype, AAV8, which had been shown to be extremely hepatotropic after systemic administration [50]. Second, the vector genome was designed as a self-complementary vector in order to bypass the synthesis of a second DNA strain after hepatocyte transduction [51]. Finally, the authors also optimized the codon usage of the transgene cDNA sequence in order to improve the efficiency of translation [52]. This vector was evaluated in a dose-escalation study in six patients with severe hemophilia B; patients have been followed for 6 to 16 months [50]. Interestingly, all patients showed a therapeutic response, which was roughly dose dependent, and with FIX levels ranging from 2 to 11% of normal. Four of six patients discontinued prophylactic FIX treatment and remained free of spontaneous hemorrhages. The remaining two patients who remained on FIX protein therapy were able to extend the time interval between prophylactic injections. Intriguingly, one of the two patients who had received the highest vector dose displayed an asymptomatic increase in serum transaminases, which coincided with the presence of AAV8-capsid specific T cells in the peripheral blood. The other patient in the same cohort also displayed a slight increase in liver enzyme levels, although the cause was less clear. Both patients received a short course of glucocorticoid therapy. As a result, serum transaminase levels quickly returned to normal, and FIX expression levels were maintained in the range of 3–11% of normal. The gene transfer vector production costs for this study have been estimated at $30,000 for a patient treated with the middle dose of vector. In light of the annual costs of protein infusion therapy, it is evident that dramatic cost reductions have already been achieved.

Taken together, these studies indicate that within the right context, AAV-mediated gene transfer to the liver has the potential to convert a severe hemophilic phenotype into milder form of the disease or even reverse it entirely. In this regard, the study by Nathwani et al. [50] is truly a landmark study in that it is the first to achieve long-term expression after systemic gene transfer to the liver at levels that are therapeutically relevant. However, in the midst of these almost euphoric results, it remains of paramount importance to remain vigilant and identify all possible factors that may influence the outcome of gene therapy in these patients. Currently, it is still unclear if

there are any risks associated with this procedure. Of note, the critical determinants of cellular immune responses directed against the AAV vector capsid are still largely unknown. It is highly likely that interindividual differences in antigen processing and presentation may influence the type and magnitude of the immunologic response against the AAV particles [53]. In addition, pre-exposure to natural AAV infections may vary highly among patients, resulting in a completely different repertoire of memory T cells. In this regard, it also remains to be determined to which extent increases in serum transaminases are clinically relevant. Finally, another question is how to optimize treatment for the large proportion of patients (up to 30% [54]) who harbor AAV8-specific antibodies. Many of these questions can only be addressed after inclusion of additional participants. If further studies indicate that this approach is safe, it may replace the cumbersome and expensive prophylactic FIX therapy. Moreover, the use of similar vectors may spark significant progress in gene therapy for other metabolic disorders, including familial hypercholesterolemia, lysosomal storage diseases, and urea cycle defects.

### 16.2.3 Leber's Congenital Amaurosis

Leber's congenital amaurosis (LCA) is a group of retinal degenerative disorders that results in early onset blindness and displays an autosomal recessive inheritance [1]. Symptoms appear during infancy or early childhood, and the diagnosis is typically made when the parents notice that the baby fails to track visually. There are no treatments available for LCA. Although there may be some low level of vision during childhood, patients eventually become completely blind by the third or fourth decade of life. To date, 14 different genes have been identified that can result in LCA [55]. In the development for gene transfer strategies to cure LCA, attention quickly moved to a variant caused by the deficiency of the gene called RPE65 (so-called type 2 LCA), which accounts for 6% of all patients with LCA [55]. This selection was mainly based on the availability of a naturally occurring dog model of LCA with RPE65 deficiency. RPE65 encodes the retinal pigment epithelium (RPE)–specific 65KDa protein, which is essential in the conversion of 11-*cis* retinal during the generation of rhodopsin in rod photoreceptors. In contrast, cone photoreceptors have access to 11-*cis* retinaldehyde chromophore through an alternative pathway that does not require RPE65. Thus, in patients with RPE65 deficiency, vision via cone photoreceptors is preserved, although progressive degeneration of rod photoreceptors eventually results in the complete loss of cone photoreceptors and, ultimately, complete blindness. However, vision could theoretically be restored by simply providing the missing enzyme, thus preventing retinal degeneration. In addition, the eye is generally regarded as an immunoprivileged site, which may prevent immunologic complications (*cfr.* the AAV2 hemophilia B trial [48]). The development of a successful therapy for LCA is regarded by many as one of the most compelling illustrations of the significant progress that has been made by the gene therapy field over the past decades.

Initial studies in genetically engineered knock-out mice and a naturally occurring dog model of RPE65 deficiency had shown the feasibility of reversing the degeneration of the retinal epithelium via subretinal injections with an AAV2 vector

encoding RPE65 [56,57]. Based on these promising findings, three groups in the United Kingdom and the United States began clinical trials for LCA caused by RPE65 deficiency in 2007. Under general anesthesia, patients received a subretinal low-dose injection of an AAV2 vector encoding the RPE65 protein in one of both eyes (generally the eye with worst function at baseline). To date, there have been no serious adverse effects in any of the more than 25 subjects who have been treated so far. Not more than 1 year after initiation of the trial, all three groups reported a certain degree of positive results in most patients who had been included in the trial. The relatively large variation in patient responses has been partly attributed to differences in vector genome structure between trials (i.e., trials in the United Kingdom used elements of the endogenous RPE65 promoter, but researchers from the Philadelphia trial used the ubiquitous cytomegalovirus promoter). Results were reported as improved psychophysical measures of visual function (including visual acuity and visual fields), as well as objective measures (e.g., pupillary light response, electroretinograms, and full-field light sensitivity) and functional measures (e.g., the ability to navigate through an obstacle course in a dimly light room) [58–60]. These beneficial effects of RPE65 gene therapy on visual function became evident as early as 2 weeks after vector injection. As was expected based on the immunoprivileged position of the eye, immune responses to the vector and the transgene product were minimal. Importantly, animal studies had previously indicated that restoration of vision after RPE65 gene therapy was most effective when performed in younger animals [61]. Although most clinical trials did not specifically assess this possible age-dependent efficacy, *post-hoc* analysis indicated that the response to subretinal gene therapy strongly corresponded to the degree of retinal degeneration at the time of injection, which had previously been shown to be strongly age dependent [60]. In the Philadelphia trial, these positive results have prompted researchers to start treating the second eye in patients who had previously been treated. Results from these studies are eagerly awaited because they will provide invaluable information on the possibility of redosing patients in the absence of immunologic complications.

In conclusion, these studies have indicated that subretinal injections of AAV vectors are safe and well tolerated. Moreover, a therapeutic effect was observed in all studies, albeit with varying success. These trials also showed that the therapeutic effect of gene transfer is highly dependent on the stage of the disease at the time of intervention. Further studies are required to assess additional variables that may influence the outcome of gene transfer studies to the retina. With regard to extrapolation of these results to other diseases of the retina and the eye, studies have indicated that whereas AAV2 can efficiently transduce cells within RPE, transduction of other cell types (including photoreceptors) is lower. Intriguingly, subretinal injection of any of the AAV serotypes tested to date can result in very efficient transduction of RPE (usually 100% transduction in the area of detachment) and variable transduction of photoreceptors (between 20% and 80% depending on the serotype and vector dose) [62]. As such, whereas interventions requiring subretinal injections are currently quite rare, the onset of gene therapy for genetic retinal disorders may lead to an increased demand among vitroretinal surgeons.

Nevertheless, an intravitreal approach allows a more homogenous transduction and poses a lower risk of surgical complications. This is also relevant for nongenetic diseases, such as age-related macular degeneration. However, it is currently unclear which AAV serotypes are most suited for this approach (see Ref. [62]). Continued progress is ongoing, and planned future trials will likely change certain practical aspects in ophthalmology [1]. Whereas identification of the underlying genetic defects in patients with hereditary retinal disorders was previously of less importance because the absence of available therapies, correct genotypic information is likely to become more important in the near future. Early detection may further be of paramount importance given the better phenotypical correction in younger patients.

### 16.2.4 Lipoprotein Lipase Deficiency

Lipoprotein lipase (LPL) is an enzyme found on the luminal surface of endothelial cells in capillaries and is mostly concentrated in adipose tissue, skeletal muscle, and the heart [63]. LPL plays a central role in the catabolism of triglyceride-rich lipoproteins, chylomicrons, and very-low density lipoproteins via hydrolysis of triglycerides into fatty acids and monoacylglycerol. In addition, LPL promotes cellular uptake of chylomicron remnants, cholesterol-rich lipoproteins, and fatty acids. Under normal conditions, LPL serves to blunt any excessive postprandial increase in triglycerides. LPL deficiency (LPLD) is an autosomal recessive disorder caused by loss of function mutations within the LPL gene, located on chromosome 8p22. To date, more than 70 different mutations in the LPL gene have been documented, and most of them are associated with loss of the catalytic activity [64]. Patients are either homozygous for these mutations or compound heterozygotes. LPLD is the most common cause of hyperchylomicronemia, with a worldwide incidence of one to two in 1,000,000, although founder effects occur in certain populations [65]. Patients present with extremely elevated levels of large chylomicrons, severe hypertriglyceridemia, and low levels of high-density lipoprotein (HDL). The most severe clinical complication is acute pancreatitis, although patients also have eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Acute pancreatitis is a heterogeneous inflammatory condition that results in significant morbidity or mortality in 20–30% of patients [66]. Currently, there is no pharmacologic treatment for LPLD, and patients are maintained on a fat-restricted diet in combination with standard lipid-lowering therapy. However, these treatments are insufficient in preventing the onset of pancreatitis and preventing complications associated with LPLD.

Gene transfer of LPL to the muscle using an AAV1 vector is being developed as a novel therapeutic to treat LPLD, and this program is sponsored by UniQure (formerly Amsterdam Molecular Therapeutics) under the name alipogene tiparvec (Glybera, AMT-011, AAV1-LPL$^{S447X}$). The final product encodes a natural gain-of-function variant of LPL that is present in 20% of whites. This variant is associated with an enhanced removal of proatherogenic apo$B_{100}$-containing lipoproteins, resulting in lower levels of low-density lipoproteins, lower triglyceride

levels, and increased levels of high-density lipoproteins or HDL cholesterol, and is associated with a decreased incidence of cardiovascular disease [67]. Animal studies in LPL-deficient mice indicated that AAV1-LPL$^{S447X}$ resulted in a persistent and dose-dependent reduction of plasma triglycerides of up to 95% [63]. Safety studies did not indicate any vector-associated toxicities.

Initiation of a clinical development program for alipogene tipoparvec in 2005 proved cumbersome; because of the low number of patients, there was a reasonable paucity of studies evaluating the natural history, presentation, and evolution of burden in LPLD patients. Therefore, the program also included prospective observational studies aimed at establishing reference values for plasma triglyceride levels, assessing the efficacy of a fat-restricted diet on LPLD-associated pathologies, and establishing a framework of safety and efficacy parameters for future intervention studies. Since then, three phase I/II and phase II/III trials have been performed in the Netherlands and Canada, including a total of 27 patients. In all studies, alipogene tipoparvec was administered as a single series of IM injections (30–70 injections depending on the body weight) in the upper and lower limbs. In selected studies, patients also received a combination of immunosuppressive drugs to inhibit immune responses aimed against the AAV1 vector. In addition to standard clinical results and data related to efficacy, these studies included analysis of vector shedding in body fluids (urine, semen, saliva) as well as immune responses directed against both the LPL transgene product and the AAV1 vector. An in-depth discussion of these results was recently published by Gaudet et al. [63]. Across the board, administration of alipogene tipoparvec was well tolerated, and none of the studies reported any dose-limiting toxicities. Long-term follow-up of patients has underscored the excellent safety profile of AAV vectors in human clinical trials. Nearly all patients showed a decrease in plasma triglyceride levels, and muscle biopsies taken 6 months after vector administration indicated persistent LPL expression and biological activity. Cox proportional hazard regression modeling indicated a 70% reduction of the risk for acute pancreatitis, although this did not reach statistical significance [63]. It is currently unclear to which extent the reduction in plasma triglyceride levels will be predictive of hard clinical endpoints. Therefore, generation of additional long-term follow up data is indicated, and patients will be followed until 15 years after vector administration for further assessments of safety and efficacy. In June of 2011, the European Medicines Agency (EMA) adopted a negative opinion, recommending refusal of the marketing approval for Glybera. The basis for this negative opinion was that studies had not shown a consistent long-lasting effect on plasma lipids and that there were insufficient patients for whom long-term follow-up data were available. After a request for reevaluation by Amsterdam Molecular Therapeutics, the Committee for Advanced Therapeutics indicated that most of the original comments could be addressed by additional postmarket studies and that approval should be granted. Nevertheless, the EMA upheld their initial objections for not granting marketing approval. As a result, the project sponsor faced severe financial turmoil, and a new private company was founded that pertained the rights to Amsterdam Molecular Therapeutics' portfolio [68]. After months of intensive discussions, UniQure was able to convince the European Commission to request a reassessment

of the marketing approval of Glybera for a specific subset of LPLD patients with multiple or severe attacks of pancreatitis. This third review by the Committee for Medicinal Products for Human Use (CHMP) again did not grant a positive opinion, although a narrow majority of the CHMP was in favor of approval. Nevertheless, UniQure was able to convince the CHMP to invite a fourth review of Glybera, which resulted in a majority vote in favor of marketing authorization on July 19, 2012. As such, Glybera became the first gene therapy product to receive marketing approval in Europe.

### 16.2.5 Heart Failure

Interestingly, the growing experience with AAV in clinical trials has also contributed to the application of gene transfer therapeutics into the field of nongenetic diseases such as heart failure. Chronic heart failure is a progressive condition in which the heart is unable to pump sufficient blood to meet the body's demands, and this remains an important cause of morbidity and mortality. Hospitalization costs in the United States because of chronic heart failure were estimated to reach more than $32 billion for 2009 [69]. The prognosis for patients with chronic heart failure remains poor, and nonpharmacologic treatments (e.g., heart transplantations and cardiac assist devices) suffer from limited availability and high costs. These restrictions have underscored the large unmet need for novel therapeutic options for patients with chronic heart failure. On the one hand, many groups have focused on cell-based therapies. However, clinical trials have struggled to show clinical benefits on hard clinical endpoints, and the isolation and selection of the desired cell populations remains a matter of debate [70]. In contrast, several recent studies have shown that gene therapy might provide an effective option for treating the failing myocardium [71,72].

One of the most common abnormalities in heart failure is a dysfunction of the sarcoplasmic reticulum, resulting in a disturbance of intracellular calcium handling. The enzyme responsible for reloading the sarcoplasmic reticulum with calcium during relaxation is the sarcoplasmic reticulum $Ca^{2+}$-ATPase (SERCA2a). Several studies have indicated that the observed dysfunction is largely attributable to a decreased activity of SERCA2a [73]. Indeed, low levels of SERCA2a have been shown to correlate with abnormally high diastolic levels of cytosolic calcium, impaired calcium release from the sarcoplasmic reticulum during systole, and poor clinical outcomes in patients with heart failure [74]. In preclinical animal models of heart failure, including rodents [75], pigs [72], and sheep [71], it has been shown that restored expression of SERCA2a protein levels after AAV-mediated gene transfer to the myocardium resulted in a significant improvement of cardiac function and energetics.

Based on these findings, a FIH phase I/II trial was initiated in 2007. The double-blind, placebo-controlled Calcium Upregulation by Percutaneous Administration of Gene therapy in Cardiac Disease (CUPID) trial aims to restore SERCA2a expression in patients with chronic heart failure. In total, 39 patients with advanced heart failure were administered an AAV1 vector encoding SERCA2a via anterograde epicardial

coronary artery infusion using standard catheterization techniques. Patients were screened for the presence of neutralizing antibodies against AAV1 before being included in one of three dose groups (low, middle, or high) and were followed for 12 months after vector administration. All patients tolerated the procedure well, and there were no untoward safety findings. Contrastingly, the incidence of adverse effects was inversely correlated to the dose of AAV1-SERCA2a. Because the possible impact of SERCA2a expression on clinical outcomes could not be predicted, this study used an endpoint approach requiring concordant changes across multiple endpoints to demonstrate efficiency. Using this methodology, the authors reported a false-positive rate of 2.7% in the placebo group [76]. Patients on placebo continuously deteriorated throughout the follow-up period. Despite some improvements at 6 months after vector administration in the low- and middle-dose groups, only the high-dose group met all of the primary endpoint success criteria. Of note, patients in the high-dose group displayed an increase in both symptomatic (New York Heart Association class, Minnesota Living with Heart Failure Questionnaire score) as well as objectively measurable (6-minute walk test, $VO_2$max, cardiac function biomarkers, and cardiac remodeling) parameters. Compared with placebo, there was also a significant reduction in the rate and duration of cardiovascular hospitalizations in patients that were treated with a high dose of AAV1-SERCA2a. All beneficial effects of gene transfer were further confirmed throughout the 12 months of follow-up. Moreover, the hazard ratios for recurrent clinical events after adjustment for terminal events indicated risk reductions of 60%, 56%, and 88% for patients who had received the low, middle, and high doses of AAV1-SERCA2a, respectively. These promising results have underscored the possibilities for a possible enhanced biological effect of SERCA2a overexpression in the setting of chronic heart failure. However, the low sample size may have led to overestimation of the results, and additional trials are required for confirmation of the observed effects. Also, long-term protection will be assessed in the current cohort to provide additional insights into the potential for gene therapy to treat advanced heart failure.

## 16.3 ADENO-ASSOCIATED VIRAL VECTORS AS A TECHNOLOGICAL PLATFORM FOR CLINICAL TRANSLATION

As discussed in the preceding paragraphs, the development of clinical gene therapy programs has relied heavily on the development of AAV vectors. Indeed, several advantageous features of AAV have identified AAV vectors as the prime candidate for a wide spectrum of different applications. Whereas some aspects of vector development apply to all of these applications, other features may be restricted to unique diseases or organs. For reasons of clarity and conciseness, the following paragraphs will focus predominantly on features that affect gene transfer to the liver. Therefore, we will first discus general aspect of the biology of AAV vectors and, whenever applicable, their development as gene therapy

vehicles for liver-directed gene transfer will be highlighted. For an in-depth discussion of alternative gene transfer vector systems and target organs, readers are referred elsewhere [1,26,31,77–79].

### 16.3.1 Adeno-Associated Viral Vectors

Adeno-associated viral vectors are small, nonenveloped, single-stranded DNA viruses belonging to the *Dependovirus* genus of the *Parvoviridae* family. After their initial identification as contaminants in laboratory preparations of recombinant adenoviral vectors more than three decades ago [80], six distinct AAV serotypes (AAV1–AAV6) were identified. Additional studies have identified an expanded family of AAV serotypes from various source materials based on the recovery of latent forms of the genome using PCR techniques. To date, 11 different serotypes comprising more than 120 capsid variants have been isolated from humans, NHPs, cows, dogs, horses, and birds [81–85]. These serotypes are categorized into six different phylogenetic clades representing a broad distribution of potential AAV biology [81]. Of these serotypes, AAV2 has been studied the most extensively and has served as a paradigm to explore AAV biology.

Compared with the genome size and structure of other viral vectors, the AAV genome is relatively small and simple, at approximately 4.7 kb, and contains only two genes, *rep* and *cap*, that encode four Rep proteins and three capsid proteins, flanked by two 145-base inverted terminal repeats (ITRs). Recombinant and replication-defective AAV vectors used for gene transfer experiments retain only the ITRs, which are necessary for replication, packaging, and integration, but all viral coding sequences are entirely removed [86].

Several favorable features have made AAV a valid candidate as a gene therapy vector. Most important, AAVs have not been associated with human disease and are thus generally considered to be nonpathogenic. This is partly reflected by the fact that most AAV variants are poor activators of both innate and adaptive immune responses. Moreover, AAVs are naturally replication defective and require co-infection with a helper virus, such as adenovirus or herpes virus, in order to replicate. In addition, AAV transduce both dividing and nondividing cells and have been shown to maintain long-term expression in the absence of chromosomal integration. Whereas wild-type AAV possess the ability for site-specific integration into the human genome, this feature is absent from recombinant AAV vectors, and integration into the host genome is random but relatively infrequent [87]. Finally, AAV2 vectors have an average diameter of 22 nm [88]. This is considerably smaller than other common viral vectors used for liver gene transfer [89,90]. Several studies have underscored the critical role of the diameter of fenestrae in restricting the passage of vectors according to their size [90,91]. Considering this potential importance of the diameter of sinusoidal fenestrae on hepatocyte transduction, the relatively small size of AAV vectors should allow efficient transendothelial passage into the space of Disse [79,89,92]. Based on the features discussed, AAV quickly moved into the forefront of the gene therapy field and a myriad of studies were initiated.

### 16.3.2 Serotype Development

The AAV capsid constitutes the primary interface between host and vector and is presumed to be the key determinant of vector tropism. The capsid is also a determinant of innate and adaptive immune responses. In the past decade, the Wilson laboratory has spearheaded the identification and characterization of novel alternative AAV serotypes [81,82]. Recent studies have underscored the supremacy of these novel serotypes *in vivo*, including increased hepatocyte transduction, reduced prevalence of neutralizing antibodies, and diminished capsid immune responses [54,93,94]. Among different serotypes evaluated to date, the most salient increase in liver transduction and transgene expression has been observed for AAV8 and AAV9 [95,96]. In general, transgene expression levels after intravenous injection in mice are increased 10- to 100-fold compared with AAV2 [82]. However, the observed advantages of AAV8 over AAV2 seem to be reduced in larger animal species such as dogs and NHPs [97,99].

Mechanisms underlying the distinct biological performance of different AAV serotypes have been attributed to differences in viral entry, trafficking, uncoating, and genome processing [100,101]. Interestingly, Cunningham et al. showed that following systemic administration of AAV8 to the liver, all dsAAV8 genomes are formed within 3 days [102]. In contrast, AAV2 shows a gradual increase of dsAAV2 genomes over a period of several weeks [103]. Nakai et al. showed that hepatocyte transduction by AAV8 does not differ after either intraportal injection or systemic administration via the tail vein and up to 90% hepatocyte transduction could be achieved [104]. Finally, AAV8 has proven to be more potent in inducing transgene-specific immune tolerance, which has been attributed to the fact that AAV8, and possibly AAV9, does not bind to heparan sulphate proteoglycan, resulting in a lower transduction of antigen-presenting cells (APCs) [105]. AAV8 has also been used with great success in different animal models of metabolic diseases [106–109].

One additional factor that may determine vector tropism *in vivo* is the use of different primary receptors between serotypes. Heparan sulphate proteoglycan has been shown to be the primary receptor for AAV2 *in vivo* [110], acting in combination with several co-receptors, including $\alpha_v\beta_5$ integrin [111], $\alpha_5\beta_1$ integrin [112], fibroblast growth factor receptor 1 [113], and hepatocyte growth factor receptor [114]. Contrastingly, AAV4 and AAV5 have been shown to primarily interact with either O-linked or N-linked $\alpha_{2-3}$ sialic acid, respectively [115]. The specific cell surface receptor for AAV5 has been identified as the platelet-derived growth factor receptor [116]. Finally, the laminin receptor has been shown to act as a receptor for multiple AAV serotypes, including AAV2, AAV3, AAV8, and AAV9 [117]. Although this might provide valuable insights into the biology of distinct AAV serotypes, the exact influence of AAV receptors in their biodistribution remains unknown.

Based on the growing knowledge of structure–function relationships of the AAV capsid, several groups have attempted to modify the AAV2 capsid to increase transduction efficiency or alter biodistribution *in vivo*. In this respect,

Vandenberghe et al. have previously demonstrated that ablation of heparin-binding motifs can modulate the antigenicity of AAV2 particles by reducing transduction of APCs [105]. Alternatively, agents that modulate the ubiquitin–proteasome system have been shown to augment nuclear trafficking of viral particles with a concurrent increase in AAV transgene expression [118]. Recently, Zhong et al. indicated that mutations of surface-exposed tyrosine residues on the AAV2 capsid can result in decreased phosphorylation and ubiquination, thereby inhibiting proteasome-mediated degradation and resulting in a 10-fold increase of transgene expression levels in mice [119]. Whereas these studies underscore the malleability of the AAV capsid, it seems unlikely that this strategy will be sufficient to overcome other disadvantageous features of AAV2, such as the high prevalence of neutralizing antibodies in humans.

In an attempt to overcome these hurdles, recent studies have focused on directed evolution techniques to screen larger AAV mutant libraries for the presence of desirable features. Using this methodology, Mahesri et al. have recently reported the selection of AAV2 variants that are more resistant to neutralizing antibodies [120]. Alternatively, Li et al. reported successful AAV capsid genome shuffling using serotype capsid sequences from AAV1, AAV2, AAV8, and AAV9 *cap* genes to select novel AAV variants for increased transduction of melanoma cells [121]. Whereas directed evolution clearly holds great promise for the generation and selection of novel AAV vectors, complete characterization of these novel variants will require extensive additional *in vivo* experiments.

### 16.3.3 Transcriptional Vector Optimization

Because the observed response in the FIX clinical trial was dose dependent, great effort has been put into increasing the therapeutic index of AAV vectors. The only viral sequences in the vector are the two ITRs, which do not seem to influence hepatocyte transduction [122]. Therefore, one important factor has been the optimization of the eukaryotic DNA sequences comprising the expression cassettes. A remarkable increase in the ratio of transgene expression per vector genome has since been achieved by using stronger promoter–enhancer combinations, by codon optimization, and by using self-complementary double-stranded AAV (scAAV) vectors. The latter is based on the ability to encode both the coding and complementary strands within a single construct, obviating the need for second strand annealing or synthesis after vector uncoating, which is the rate-limiting step in initiating transgene expression [51,123]. However, in a recent series of experiments, Gao et al. have shown that the improved transduction efficiency of hepatocytes by scAAV can be highly context dependent [124,125]. Possible explanations for these observations include differences in transcriptional activity between ssAAV and scAAV genomes, differences in vector design, and the presence of neutralizing antibodies in NHPs. Irrespective of the underlying cause of these discrepancies, the inferred 50% reduction in vector packaging capacity has restricted the use of scAAV to a very limited number of transgenes.

The most pronounced improvements in transgene expression have been obtained by using different promoter–enhancer combinations. Although unique studies performing side-by-side comparisons are rare, several studies have indicated that the most potent promoters for hepatocyte-restricted expression are the *albumin* promoter [126], the α1-antitrypsin promoter [127], and the thyroxine-binding globuline promoter [99,108]. Franco et al. showed that the synthetic 790 bp LSP promoter, consisting of the 475 bp thyroxine-binding globuline promoter and two copies of the 96 bp bikunin/$\alpha_1$-microglobulin enhancer, resulted in 60-fold higher transgene expression levels compared with the constitutive cytomegalovirus enhancer/chicken β-actin promoter [107]. Other strategies to improve the efficiency of transgene expression have been aimed at optimization of transcriptional sequences by inclusion of an optimized Kozak consensus sequence or via codon optimization of the transgene sequence. A consensus Kozak sequence has been shown to be important and required for the optimal translation of mammalian genes by enhancing the recognition by eukaryotic ribosomes [128]. Similarly, rare codon usage may result in translational stall caused by tRNA unavailability, and overrepresented codon pairs may stall because of ribosome pausing [129]. Conversely, underrepresented codon pairs may enhance translational efficiency of a transcript. The rate of translation can also affect protein folding, and it has been suggested that codon usage may be a mechanism to regulate translation speed and thus allow stepwise folding of individual protein domains [130]. Although *lege artis* comparisons in gene therapy experiments are scarce, several studies have shown significant improvements in transgene expression by combining these techniques [52,106,131,132]. Finally, several studies have documented a significant increase in transgene expression after inclusion of the woodchuck hepatitis posttranscriptional element (WPRE) [133,134]. Although the specific mechanism of this enhancement is not well described, this may involve the facilitation of RNA processing and RNA export [135,136]. However, a potential oncogenic activity of the WPRE sequence, because of potential promoter activity and the possibility of expressing a 60-amino-acid woodchuck hepatitis virus X protein-derived peptide, might preclude the incorporation of this DNA sequence in clinical applications [137].

### 16.3.4 Selection of Animal Models for Liver-Directed Gene Transfer

A critical factor in progress toward clinical applications of gene therapy is the availability of animal models that accurately predict outcomes in humans. Unfortunately, extrapolation of data from murine studies to larger animal species has been cumbersome. Complications observed in larger animal species include reduced hepatocyte transduction, a higher prevalence of neutralizing antibodies against the vector, and a higher susceptibility for cellular immune responses toward the transgene or the AAV capsid.

Notably, several studies have indicated that whereas AAV8 is more potent in targeting the liver than AAV2, the observed increment in transgene expression in larger animal models is markedly reduced compared with mice. Based on data from dogs, it was previously estimated that AAV8 is about 1.5- to 4.3-fold more efficient

than AAV2 and two- to sevenfold more efficient than AAV5 for hepatic gene transfer [99]. Interestingly, Davidoff et al. showed that in mice, hepatocyte transduction by AAV was also five- to 13-fold higher in males compared with females, irrespective of the promoter, transgene sequence, or mouse strain [138]. Similar findings have since been observed in several mouse models of metabolic diseases [139–141]. Unfortunately, differences in liver transduction between males and females in larger species have remained largely unaddressed, mostly because of low sample sizes. As such, this might partly contribute to the relatively high degree of variation observed in higher species. An additional critical factor that should be taken into account is that whereas pre-exposure to AAV8 can be low in humans, the prevalence of neutralizing antibodies against this serotype are much higher in NHPs because they are the natural hosts. As such, even very low levels of neutralizing antibodies that are below the detection limit of current modes of analysis have been implicated in reduced hepatocyte transduction in NHPs. However other causes should also be taken into account, and in this respect, Gao et al. recently showed substantial differential processing of AAV genomes in mice and NHPs [142]. Nevertheless, gene transfer in both the FIX clinical trials resulted in clinically relevant transgene expression levels of 10–12%, which is comparable to dogs injected with an identical doses. Thus, it seems that if immunologic complications can be prevented, data obtained in dogs and possibly NHPs might be directly translatable to humans. In this respect, Nathwani et al. recently documented an almost linear dose-response curve after intravenous administration of an scAAV8 vector in NHPs [143]. Remarkably, gene transfer with a dose of $2 \times 10^{12}$ v.g./kg was sufficient to transduce almost 100% of hepatocytes, resulting in supraphysiological transgene expression levels for up to 5 years.

Taken together, these data underscore the great progress that has been made in evaluating the efficiency of AAV vectors in cats, dogs, and NHPs. However, even when stringent precautions are taken, some studies have shown unexpected complications for reasons that remain largely enigmatic. Identification of additional factors that may influence gene transfer efficiency in larger animals is of paramount importance for improving clinical applicability.

## 16.4 CHALLENGES IN HEPATOCYTE-DIRECTED GENE THERAPY

The liver is the largest internal organ of the human body and plays a central role in protein synthesis, detoxification processes, and metabolism. In addition, the liver is highly vascularized, with almost 30% of the total blood volume passing through the liver every minute, thereby facilitating efficient secretion of therapeutic transgenes produced by transduced hepatocytes. As such, parenchymal liver cells (i.e., hepatocytes) constitute a key target for therapeutic strategies aimed at correction of inborn errors of metabolism. A global overview of preclinical studies using AAV gene transfer for the correction of metabolic diseases has been described previously [16,144]. Here, we discuss the most important remaining hurdles that might impede efficient clinical translation (Fig. 16.2).

**FIGURE 16.2** Key determinants of efficient and persistent liver gene transfer with adeno-associated viral (AAV) vectors. Sustained therapeutic corrections depend on efficient hepatocyte transduction and the maintenance of persistent transgene expression. Whether or not these goals are met depends on an intricate interplay of different factors. Preexisting neutralizing antibodies greatly impair hepatocyte transduction. In addition, pathological sequelae of the liver, such as inflammation or pseudocapillarization, may also interfere with hepatocyte transduction or contribute to the priming of reactive T cells. Whereas hepatic transgene expression may induce a tolerogenic state, immune activation can also lead to the priming of a cytotoxic T-cell response or the formation of inhibitory antibodies. In pediatric patients, fast liver growth leads to a concomitant decline in transgene expression. Finally, vector design greatly influences the outcome of liver gene transfer strategies. (Adapted from Ref. [16].)

### 16.4.1 Role of Pre-exposure to Natural Adeno-Associated Viral Infections

Prior exposure to AAV has been shown in many species, including mice, dogs, NHPs, and humans. These infections result in the formation of complex profiles of serum antibodies capable of binding and neutralizing various AAV serotypes (see Fig. 16.2) [54,145]. Although human data on the effects of neutralizing antibodies on hepatocyte transduction are scarce, the absence of efficient transduction in at least one patient of the AAV2 FIX clinical trial was attributed to the higher level of neutralizing antibodies [48].

Original reports showed that a large proportion of the human population has been exposed to AAV, with at least one-third having neutralizing antibodies against AAV2

[146]. Importantly, Halbert et al. showed that in pediatric patients with cystic fibrosis, neutralizing antibodies against several AAV serotypes are remarkably lower [147]. In a recent study by the Wilson group, the authors analyzed serum samples from 888 persons, spanning four continents and 10 different countries, for the presence of neutralizing antibodies directed against a wide array of AAV serotypes [54]. In most regions, the prevalence of clinically relevant titers of neutralizing antibodies was lowest for AAV7 (15–30%) and AAV8 (15–30%). In contrast, neutralizing antibody titers against AAV1 (20–45%) and AAV2 (30–60%) were significantly more prevalent. The observed differences in seroprevalence against distinct serotypes most likely reflect their natural host tropism. Humans are not commonly pre-exposed to serotypes derived from NHPs, resulting in lower titers of neutralizing antibodies. Finally, a significant degree of co-prevalence of neutralizing antibodies against different serotypes has been observed, indicating the general breadth of neutralizing antibodies against AAV in humans. A survey of human plasma samples on preexisting neutralizing antibodies suggests that 75% of the population of the United States has sufficiently low levels of neutralizing antibodies against AAV8 to achieve a possible clinical effect after systemic gene transfer. However, even these low levels of neutralizing antibodies can significantly inhibit cell transduction after systemic administration. Alternatively, the use of plasmapheresis in diminishing neutralizing antibodies to viruses has been explored [148]. This could be a strategy for converting some of the AAV8-resistant patients to those eligible for AAV8 gene transfer. Alternatively, animal studies have indicated that interference by low titers of neutralizing antibodies could be overcome by a 10-fold increase in the vector dose [149]. Based on these results, it was estimated that high-dose gene transfer with AAV8 would successfully transduce the liver in 50% of human patients (i.e., in patients who are truly AAV8 antibody negative). In addition, temporary depletion of neutralizing antibodies by plasmapheresis was predicted to increase this to roughly 90%.

However, detection of neutralizing antibodies remains somewhat cumbersome because of technological challenges and the lack of standardization. One common assay to quantify the effects of neutralizing antibodies is *in vitro* inhibition of transduction. However, most novel serotypes poorly transduce cells *in vitro*, requiring high multiplicities of infection to achieve detectable transgene expression levels. In addition, interactions of AAV with antibodies in the presence of serum proteins may not be accurately mimicked *in vitro*, further complicating interpretation of these assays. Detection of AAV-binding neutralizing antibodies can also be performed by ELISA, although this method may not accurately predict whether or not transduction by AAV will be inhibited *in vivo*. Alternatively, the effect of neutralizing antibodies on hepatocyte transduction has been assessed by passive transfusions of sera into naïve mice in order to overcome the issue of low sensitivity of the *in vitro* inhibition assay.

In conclusion, although preexisting vector-specific antibodies represent an important hurdle for clinical translation, overcoming pre-immunization may be insufficient for guaranteeing clinically relevant transgene expression levels. Additional methods that increase transgene expression by AAV vectors (see below) remain of paramount importance in advancing toward clinical applications.

### 16.4.2 Immunologic Complications

***16.4.2.1 Immune Responses Toward Adeno-Associated Viral–Encoded Transgene Products*** Immune responses toward AAV-encoded transgene products are determined by an intricate balance between mechanisms of tolerance and immune activation. The end result will be determined by various factors that influence interaction between AAV and the host (see Fig. 16.2). Several mechanisms have been proposed to address the apparent tolerance toward AAV-encoded transgene products after liver-directed gene transfer. A critical factor is the low activation of innate immunity by AAV, which, together with the low degree of APC transduction, results in impaired activation and maturation of APCs as well as reduced expression of co-stimulatory molecules [150]. As a result of poor innate immunity induced by AAV, APCs, such as macrophages and dendritic cells, do not mature properly, thereby reducing their ability to take up, process, and present antigen. Absence of inflammatory signals after AAV exposure reduces antigen presentation on APCs and hepatocytes, resulting in impaired T-cell priming and reduced targeting of hepatocytes by cytotoxic T cells, respectively [151]. Finally, low transduction of APCs by AAV further decreases the amount of available antigen required to prime naive T cells [152]. Several studies have shown that although AAVs are capable of priming potent $CD8^+$ T-cell responses toward transgene, lack of co-stimulatory signals can result in impaired proliferation and cytokine secretion. Thus, in the absence of additional inflammatory signals, AAV results in the generation of immunologic tolerance via mechanisms of ignorance, anergy, or deletion.

However, depending on the context, an appropriate degree of inflammation can be reached that is sufficient to break AAV-induced tolerance, resulting in robust and functional $CD4^+$ and $CD8^+$ T-cell responses. Factors determining whether this threshold is reached include the vector dose, the route of administration, the serotype, preexisting immunity to AAV, the transgene, the promoter, and the host species [153,154]. This might be of particular importance for secreted proteins because uptake by APCs can result in presentation onto MHCI via a process known as "cross-presentation," possibly leading to $CD8^+$ T-cell priming. Importantly, several studies have underscored the more tolerogenic nature of the liver in maintaining persistent high transgene expression after AAV gene transfer. This ability of antigen expression in the liver to induce tolerance has been shown most convincingly in the setting of allogeneic liver transplantations, showing spontaneous acceptance of liver grafts in the absence of immunosuppression as well as induction of tolerance toward other co-transplanted organs [155]. Recent studies using novel AAV variants show that serotype capsids may also play an important role in the activation of immunity [156]. This has largely been attributed to differences in the transduction of dendritic cells by distinct serotypes. Alternatively, differences in innate immune responses elicited by different serotypes could affect their propensity to activate adaptive immunity. Nevertheless, even if the threshold for initiating a T-cell response is reached, mechanisms of active suppression may still come into play that dictate the priming of either effector T cells or suppressors. In this scenario, the micro-environment of the liver has been shown to favor production of cytokines that result

in the generation of a population of $CD4^+$ $CD25^+$ $Foxp3^+$ Treg suppressors [47,157]. However, tolerance to transgene products after AAV gene transfer appears to be more difficult to establish in large animal models. Although long-term expression of green fluorescent protein (GFP) has been easily achieved in different tissues in mice, GFP expression in the livers of macaques is only short lived or significantly reduced even with a liver-specific promoter, and animals developed $CD8^+$ T cells to GFP [124,158]. Future studies will be aimed at further elucidating the underlying mechanism that determines the threshold between establishing tolerance and generating immunity.

***16.4.2.2 Immune Responses Toward Adeno-Associated Viral Capsids*** Whereas preclinical studies with AAV2 in animal models generally resulted in persistent transgene expression, the FIX clinical trial highlighted the intricate interplay between the vector and the human immune system. Although the underlying mechanisms of these observations remain elusive, several theories have tried to address these observations [154,159]. Mingozzi et al. put forward the hypothesis that preexposure to AAV in humans may have resulted in the generation and maintenance of a small pool of $CD8^+$ memory T cells directed against the AAV2 capsid (Fig. 16.3) [159]. Because AAV2 is endemic in humans and pre-exposure occurs mostly in combination with infection of an adenovirus, this combination may trigger the innate immune system more avidly than AAV2 alone, thus exceeding the threshold for active immunity toward AAV2. Although studies substantiating these claims in humans are scarce, epidemiologic data indicate that up to 60% of the population might harbor a capsid-specific memory T-cell population [49]. After reexposure to AAV2 capsid, these memory T cells are readily reactivated, resulting in elimination of transduced hepatocytes that present peptides derived from capsid protein. One common problem in testing this hypothesis has been the inability to model the elimination of transduced hepatocytes by cytotoxic T cells in animal models. The absence of pre-exposure to AAV2 in most animal models would explain why vigorous T-cell responses toward capsid were not observed in preclinical studies. Preexisting immunity in mice has been simulated using immunization by adenoviral vectors expressing AAV capsid proteins as well as direct delivery of AAV vectors. Although T cells generated using these methodologies have been shown to be fully functional, they are unable to target and eliminate hepatocytes that have been transduced by AAV *in vivo* [94,160–162]. Nonetheless, presentation of the exogenous capsid derived from input AAV particles onto MHCI, followed by priming of a cytotoxic T-cell response, has been shown to occur in both mice and cynomolgus macaques [105,160,163]. Possible explanations for the observed higher threshold for cytotoxic T-cell clearance of hepatocytes in mice include increased responsiveness of human T cells to T-cell receptor stimulation, more efficient homing of human T cells to the liver, lack of efficient cross-presentation of AAV capsid antigen in mouse hepatocytes, and the fact that in humans cytotoxic T cells originate from a pool of memory $CD8^+$ T cells in contrast to AAV-primed $CD8^+$ T cells that are activated in mice [49].

**FIGURE 16.3** Working hypothesis for the observed immunological activation in the AAV2 FIX clinical trial. Mingozzi and King [1] have put forward the "memory T-cell" hypothesis to explain the transient expression of factor IX (FIX) protein after systemic administration of adeno-associated viral 2 (AAV2) vectors. A proportion of humans have been shown to maintain a small population of memory $CD8^+$ T cells after natural infections with AAV2. In the context of the gene therapy trial, systemic reexposure to the AAV2 vector resulted in vector uptake by APCs. Capsid proteins are presented onto major histocompatibility (MHC) class II molecules, resulting in the activation of $CD4^+$ T cells and the production of inflammatory cytokines. This leads to an expansion of the memory $CD8^+$ T-cell pool. Concomitantly, transduction of hepatocytes occurs by receptor-mediated endocytosis in clathrin-coated pits. After endosomal escape, capsid proteins are ubiquitylated and proteosomally degradaded. The resulting peptides can be loaded onto MHC class I molecules via a "cross-priming" mechanism and are subsequently presented on the cell surface. As such, hepatocytes are flagged as targets for recognition by activated cytotoxic $CD8^+$ T cells, which may subsequently lead to the elimination of transduced cells and the loss of transgene expression.

Whatever the cause may be, based on the lack of data substantiating the capsid memory T-cell response, alternative hypotheses have been put forward. Vandenberghe et al. proposed a mechanism in which a specific heparin-binding motif on the AAV2 capsid favors transduction of human dendritic cells, thus facilitating activation of capsid specific $CD8^+$ T-cells [105]. As demonstrated in mice and NHPs, native or engineered AAV serotypes devoid of this motif are able to circumvent the generation of capsid-specific $CD8^+$ T-cells [94,105]. However, the usefulness of non–heparin-binding serotypes in overcoming capsid T-cell activation has recently been questioned [161,164]. It has been hypothesized that because of the high degree of homology between AAV serotypes and the conservation of the potential immunoreactive epitopes in AAV2 capsid, exposure to these serotypes may still result in activation of $CD8^+$ memory T cells [49]. Nevertheless, we believe that serotypes with reduced immunogenicity add a safety measure for clinical applications.

Alternatively, packaging of residual plasmid expressing capsid during vector production may have resulted in continuous expression of capsid proteins. However,

to date, it has not been possible to show *de novo* capsid protein expression after AAV transduction *in vitro*, and animal studies have not shown any evidence of capsid expression [165]. In contrast, Gao et al. recently showed low-level expression of *cap* gene in liver in NHPs caused by the presence of both endogenous AAV genomes and those derived from the preparations of the vectors caused by contamination with the *trans*-packaging plasmid [124]. Although the authors could not discern between both sources of cap expression, this seems irrelevant in terms of activating T cells or rendering hepatocytes targets for cytotoxic T cells because no such T cells were activated in this study. Finally, although no $CD8^+$ T-cell response against FIX was detected in the clinical trial, one recent study in mice reported the transcription of cryptic neo-epitopes encoded from an alternative open reading frame of the *FIX* gene [166].

### 16.4.3 Neonatal and Pediatric Gene Therapy

Because most metabolic diseases manifest at a young age, specific interest should be given to factors that may influence the potency of AAV in this population. Importantly, several lines of evidence indicate that hepatocyte transduction may be more efficient in younger patients. Of note, the presence of neutralizing antibodies has been shown to be reduced in pediatric patients [147]. An additional important safety concern is that in most pediatric patients, there is less tissue damage or accumulation of toxic metabolites, possibly reducing the threshold for therapeutic efficiency (see Fig. 16.2). Moreover, this reduced inflammation may be of paramount importance in evading transgene specific immune responses. In this regard, studies in neonatal dogs and cats have shown great efficiency in preventing the onset of pathologies.

A particular concern of pediatric gene transfer strategies is the potential impact of liver growth on transgene DNA persistence. Most AAV genomes reside within the nucleus in an episomal form. As a result, transgene DNA is lost during mitosis when the nuclear envelope is degraded. In the adult mouse liver, individual hepatocytes are slowly dividing, completing a single population turnover every 180 to 400 days [167]. Consequently, a rapid decline of transgene expression has been observed in the context of rapid hepatocyte proliferation after AAV administration into neonatal mice [102,168]. Interestingly, when vector is delivered at serially higher ages up to adulthood, transgene expression is progressively more durable, correlating with the slowing of liver growth [102]. Taken together, these studies indicate that proliferation of hepatocytes results in a nearly complete clearance of AAV genomes from the liver within two population doublings, corresponding to a time frame of 1 to 2 weeks in mice [102,106,168,169].

The remaining question is to which extent these results can be extrapolated to other species. It seems straightforward that hepatocyte proliferation will result in substantial loss of transgene DNA irrespective of the species studied. Nevertheless, this process is likely to be substantially slower in larger models. In this respect, neonatal gene transfer has recently been shown to result in long-term correction in a feline model of mucoplysaccharidosis type VI or Maroteaux-Lamy syndrome (MPS VI) [170]. As

for humans, it is estimated that a first doubling of the liver mass occurs within 9 months after birth followed by a second doubling in mass taking up to 3 to 4 years [171]. By inference from mouse data, Cunningham et al. [102] estimated that at similar levels of episome clearance with each doubling of liver mass, therapeutic transgene expression in humans would be expected to fall substantially by the end of the first year of life if administered at the neonatal stage. Thus, depending on the levels of transgene expression required for therapeutic benefit, vector readministration is likely to be necessary. Several groups have indeed underscored the possibility of using distinct AAV serotypes to circumvent preexisting immunity [99,172,173].

## 16.5 REGULATORY ASPECTS OF GENE THERAPY

The swift progress of various gene therapy applications into the clinic has also highlighted another critical issue within the community: a general lack in regulatory experience and a relative vacuum of regulatory guidelines for these continuously changing gene therapy technologies [174,175]. From a regulatory aspect, gene therapy products represent one of the most complex classes of therapeutics, combining both elements of nucleic acids as well as a complex mix of proteins. As a result, the development of gene therapy products is highly regulated, and development of a gene therapy drug into the clinic is associated with unique challenges. Although this can sometimes be a quite frustrating and overwhelming process, it is imperative for researchers to collaborate with regulatory agencies early on in the developmental process to avoid unnecessary delays in the development of gene therapy products. Indeed, regulatory guidelines are not legally binding but rather represent the current vision of regulatory agencies at that time. As such, regulators should be regarded as collaborators whose comments can significantly help expedite the product development. As will be discussed in the following paragraphs, the concerted goal of these organizations is to ensure the safety of both the study participants and the researchers themselves by ensuring that proper guidelines for vector production (GMP) and the conduct of the clinical trials (GCP) are stringently followed. As such, the regulation of clinical gene therapy trials combines aspects related to both production and characterization of the clinical product, as well as ethical considerations related to study of human participants [11].

### 16.5.1 Guidelines and Regulatory Organizations

Regulatory bodies that are responsible for the oversight of clinical gene therapy trials are organized in several national and supranational organizations [174,176]. In the United States, all clinical trials are supervised by the Department of Health and Human Services. However, the final responsibility is further shared across different regulatory organs, and a centralized oversight is lacking. As such, research subjects fall under the protection of the Office for Human Research Protection (OHRP), but the Food and Drug Administration (FDA) has specific oversight of the therapeutic gene therapy products. Therefore, before proceeding with the clinical use of any

unlicensed gene therapy product, the investigators must submit an Investigational New Drug (IND) application with the FDA. The FDA reviews all facets of gene therapy trials, including preclinical efficacy, toxicology, product manufacture and certification, and the design and conduct of the clinical trial. The OHRP further mandates that all research involving human subjects undergo full review and approval by an institutional review board (IRB). The IRB is responsible for evaluating the research risk for study participants and must review the clinical study protocol and informed consent documentation before initiation of the study.

Of note, any clinical trial that is supported by funding from the National Institutes of Health (NIH) will also be placed under oversight by the NIH, which is performed by the Office of Biotechnological Activities (OBA). However, final responsibilities are further taken over by the Recombinant DNA Advisory Committee (RAC) and the Institutional Biosafety Committee (IBC). The RAC aims to develop specific policies and regulations for performing research involving recombinant DNA molecules, with a specific emphasis on safety and scientific conduct. On the other hand, the role of the IBC is to assess possible risks to the public and to review individual research protocol as well as to ensure compliance with NIH guidelines. Final oversight is performed by the OBA, which is charged with the federal oversight of all IBCs and performs direct monitoring and review via the RAC. Importantly, the RAC does not approve clinical protocols but provides suggestions for revisions to address scientific, ethical, or legal comments. Before initiation of any trial, the FDA will oversee a complete review of the proposed IND.

In Europe, the responsibility for approval and review of clinical gene therapy trials is predominantly the responsibility of the member states of the European Union. The application for approval starts with the submission of the Investigational Medicinal Product Dossier (IMPD) to the responsible national agency (see complete list: http://www.hma.eu). This IMPD contains a complete description of all facets of the proposed trials, including a project description, available preclinical data, study rationale, detailed experimental procedures, materials, assessment of pharmaceutical quality, and a formal biosafety evaluation. In addition, a complete description of the scheduled clinical trial must be submitted to the appropriate ethical committee. Although the European Union has implemented certain guidelines (e.g., Directive 2001/20/EC) to harmonize procedures for authorizing clinical trials across member states, the detailed procedures remain somewhat different [176]. Furthermore, laws and regulations pertaining to the use and deliberate release of genetically modified organisms (GMOs) and the use of stem cells also differ in among member states, further complicating a synchronized program for developing gene therapy products across the European Union. Whereas some member states regard gene transfer vectors as a deliberate release of GMOs (in line with Directive 2001/18/EC), others regard them as GMOs for contained release (according to Directive 2009/41/EC). Although both directives aim to protect the individuals and their environment, these differences in classifications significantly impact on the design and the review period of the application. Unfortunately, Europe lacks a centralized regulatory organ with an independence and accountability similar to the RAC. However, to further assist in the development of gene therapeutics, the European Union has set up specific provisions

such as that gene therapy products can be developed under the orphan drug designation by the European Commission [11]. In addition, the European Union has funded the CliniGene Network of Excellence (NoE) to further support researchers to perform high-quality gene transfer research and its translation into successful clinical trials. Nevertheless, a more centralized expert review within the European Union would be more efficient and less time consuming and could help circumvent a relative lack of critical gene therapy research expertise in certain member states [177].

Although there are some important distinctions in the organization of these regulatory instances, final review of the submission is subject to similar obstacles in both the Unites States as in Europe. Of note, review bodies may lack experience and expertise in the science of gene therapy, increasing the likelihood that oversight could fail to address the most salient issues while giving excessive attention to less important aspects of gene therapy research [177]. Similarly, many (if not most) gene therapy products are being developed by investigators at nonprofit research institutions, which may lack the necessary experience in dealing with regulatory instances. Finally, the increasing clinical experience with viral gene transfer vectors also directly impacts on the regulatory review of future studies. On the positive end, this increasing experience may help create an extensive regulatory framework that can help facilitate future submissions. On the other hand, new studies may also highlight novel pitfalls or complications, underscoring the need for additional safety guidelines and regulations. In light of the complexity of these regulatory aspects of gene therapy products, a continuous reexamination of the ethical issues surrounding the application of gene therapy into clinical practice is warranted.

### 16.5.2 Vector Production and Product Characterization

The shift toward large-animal studies and first generations of clinical trials has led to a significant increase in vector needs. However, production of purified AAV vectors at the required scale has proven to be difficult to scale up, relying on highly technical and costly procedures. To overcome this impediment, several recent innovative production systems have been developed that are compatible with large-scale production for clinical applications [178–180]. These new systems use adenovirus, herpesvirus, and baculovirus hybrids to deliver the AAV genome and *trans*-acting helper functions to producer cells. Irrespective of the modus of production, several recent studies have identified vector purification methods as a key determinant of vector potency *in vivo* [181,182]. Increasing vector purity and potency is predicted to reduce the risk of deleterious immune responses after administration of recombinant AAV to human subjects. Standard purification of AAV vectors requires multiple rounds of CsCl ultracentrifugation. However, these gradients are limited in terms of their loading capacity, and prolonged exposure to CsCl has been reported to compromise AAV vector potency. Large-scale purification of AAV has been based on ion-exchange chromatography, hydrophobic interaction, and affinity purification methods, resulting in increased purity, yields, and scalability. However, these methods are generally serotype dependent and lack the ability to discern between

fully functional AAV particles and empty capsids. In contrast, density centrifugation using iodixanol gradients effectively separates infectious particles from empty capsids, a desirable property for reducing toxicity and unwanted immune responses during preclinical studies [182]. Finally, an important question remains regarding which criteria accurately predict the overall quality of different vector lots. Several parameters have been developed to further characterize purified AAV stocks, including silver staining of SDS-PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis) separation of proteins, ratio of rAAV full capsids to infectious particles, protein contamination, and DNA contamination. However, although these analyses focus predominantly on physical features of the vector preparations that are easily standardized, further studies are needed to assess the validity of these parameters as predictors of vector potency and safety *in vivo*.

Before any gene therapy product can be formally tested in clinical trials, the production methods must be standardized in order to comply with the GMP standards. These standards are a set of scientific methods, principles, or practices that should be implemented during production to ensure the consistent manufacturing of safe, pure, and potent products. The emphasis of GMP guidelines lies in documentation and traceability. As discussed by Laurencot et al. [183], the highly complex biological nature of gene therapy vectors represents numerous manufacturing challenges. Therefore, the FDA may not require full GMP compliance during all stages of development but rather an incremental approach during the different phases of development (i.e., the so-called "sliding scale" of GMP) [183]. Nevertheless, manufacturing of gene therapy products according to GMP standards for clinical trials can be one of the biggest hurdles to overcome. For these reasons, it is quite common that this process will be contracted out to a registered GMP facility that already has relevant expertise.

## 16.6 GENERAL CONCLUSIONS AND PERSPECTIVES

The past decades have seen several successes in the gene therapy field. However, optimism must be tempered with caution. Indeed, despite the significant progress, many important obstacles remain that might impede widespread application of gene therapy applications in clinical practice. The success of gene therapy depends on a multitude of parameters. Although some of these parameters are universally relevant for different diseases, others are highly dependent on the disease, the target tissue, or the transgene. In this regard, most studies have underscored the direct impact of the stage of the disease at the time of intervention on the final therapeutic outcome. Therefore, it is likely that optimal age ranges and disease classifications may need to be established, which could be extremely disease specific. However, this also leads to several ethical dilemmas. Given the risk of insertional mutagenesis and genotoxicity of most vector systems, the relative paucity of studies including long-term follow-up precludes adequate risk assessments. In addition, data on viral shedding have indicated the presence of transgene DNA sequences in semen, raising concerns over inadvertent germline transmission [177]. These concerns are of specific interest

when discussing the eligibility of young children for gene therapy approaches. Given the fact that preliminary data indicate that the possible therapeutic effects of gene transfer may be more pronounced when pathological conditions are reversed early in the disease progression, one important question is when gene therapy approaches should be considered. Is it wise to compromise patients safety in order to achieve maximal therapeutic effects or should gene therapy only be considered as a last resort, even if this can limit the possible therapeutic effect [177]? In other words, should priority be given to safety or efficacy?

Alternatively, the development of immune responses directed against the gene therapy vector or the therapeutic transgene remains an important safety issue. Although several factors that can influence the degree of immune stimulation have been identified (e.g., vector dose, route of administration, vector type, type of transgene, target tissue), their respective roles remain largely enigmatic. The immunostimulatory role of viral gene transfer vectors is also of great importance for certain applications that may require repeated vector administrations because the formation of a neutralizing antibody response will preclude efficient transduction upon readministration of the vector. To overcome these immunologic hurdles, several groups are aiming to minimize the immunogenic risk by using lower vector doses or administration of immunosuppressive drug regimens. These strategies are currently under investigation in clinical trials, which will indicate if these interventions also translate into improved clinical benefits.

Finally, one of the remaining hurdles for the gene therapy remains the development of successful business models to encourage the participation of the biotech industry in the development of commercial gene therapy products [184]. Indeed, whereas commercial biotech companies played a important role in the early development of gene therapy products, this interest has gradually faded because of the significant setbacks highlighted in this chapter as well as the high cost and long timelines associated with the development process. As a result, early companies eventually failed to generate sufficient capital to maintain their investments. Now the emerging positive results from clinical gene therapy trials may spark novel interest by the biotech industry. Almost every venture capital firm and biopharmaceutical company is currently reevaluating the possible commercial value of gene therapy products [9]. This new interest can help provide two scarce resources to the gene therapy field: regulatory experience and financial support. Interestingly, important concerns are not related to technical feasibility but rather to the uncertainty of regulatory processes and concerns about the business model. As illustrated by the lengthy and tortuous approval applications for Glybera, achieving the final goal of reaching marketing approval can be very costly and must be pursued without any guarantees for success. Even though there are currently almost no approved gene therapy products in Europe and the United States, the development of gene therapy products is moving forward with enthusiasm. The question thus remains how to develop a model that is robust enough to provide a balance between profitability (for developers and investors) and affordability (for patients and government agencies) [184].

In conclusion, the field of gene therapy has matured significantly over the past decades. Early hype, failures, and tragic events have largely been replaced by the

necessary stepwise progress needed to realize clinical benefits. The fruits of these efforts are now showing in the first generation of successful clinical trials. Of note, the developmental timeline of gene therapy products is comparable to other novel therapies such as bone marrow transplantations and monoclonal antibody therapies. However, amid these invigorating times, it will be of paramount importance to remain focused on the continuous refinement of gene transfer technologies and the identification of hitherto unknown complications. The importance of these refinements is exemplified by more recent successes, such as the use of novel generation lentiviral vectors for the treatment of adrenoleukodystrophy [185] and of AAV8 vectors for the treatment of hemophilia B [50]. Although it is tempting to quickly move such advancements forward into the clinic, great caution must be taken not to impede on benefits to patients in the long term. With increasing experience, the gene therapy field will continue to mature in order to certify an ordered and timely transition from bench to bedside.

# Nucleic Acid Vaccines

RACHEL BUGLIONE-CORBETT, JOHN SUSCHAK,
SHIXIA WANG, and SHAN LU

## 17.1 INTRODUCTION

In 1796, Edward Jenner made the first demonstration of human vaccination against a pathogen using cowpox to inoculate subjects against smallpox. In the centuries that followed, smallpox has been eradicated in human populations and the principles and effectiveness of vaccination have been firmly established, yet the emergence of new pathogens has constantly challenged scientists to develop new vaccination technologies for improved safety and efficacy.

In many cases, new vaccine technology surges forward as an epidemic looms and an urgent demand develops. In the first half of the 20th century, poliovirus infection spread throughout the world. By early 1950, poliovirus infection in the United States left thousands dead and thousands more disabled. In response to this public health threat, Jonas Salk's inactivated virus vaccine and Albert Sabin's live-attenuated virus vaccine were developed in 1952 and 1958, respectively, drastically controlling the incidence of polio worldwide, further confirming the power of these two types of the first-generation vaccines [1].

With improved public health surveillance and better diagnostic tests, additional emerging viral infections were discovered after World War II, including a number of hepatitis viruses. Taking advantage of the recombinant protein technology, subunit-based hepatitis B virus (HBV) vaccines were developed in the 1980s, which proved to be a successful example of the second generation of vaccines [2–4].

However, the emergence of new pathogens, such as human immunodeficiency virus (HIV), around the same time when an HBV recombinant protein vaccine was licensed indicated that additional new vaccination technology was needed. Subunit protein-based HIV vaccines alone failed to protect in phase III efficacy trials [5,6], and the concern about the safety and efficacy of the first-generation vaccines

(live-attenuated and inactivated vaccines) prevented much effort in using them for HIV vaccine development.

## 17.2 HISTORY OF NUCLEIC ACID VACCINES

### 17.2.1 Early Discovery of DNA Vaccines

In the early 1990s, the demonstration of effective DNA immunization in animal models changed the paradigm of vaccine technology. For the first time, genes encoding antigens, instead of antigens themselves, were demonstrated to elicit a broad spectrum of immune responses against antigens from a variety of pathogens. The efficacy of DNA vaccination was demonstrated first in small animal models and nonhuman primates (NHPs) against pathogens including HIV-1 [7–10], rabies [11,12], HBV [13–15], bovine herpesvirus 1 [16], tuberculosis [17], and influenza [18–21]. Immunogenicity and efficacy have since been tested in human trials, including vaccines against pathogens that include HIV-1 [22–26], HBV [27], and malaria [28–31], as well as in antitumor DNA vaccinations [32,33].

DNA vaccination provides several advantages over other established vaccination strategies. The antigen of interest is produced endogenously and presented to the immune system without danger of toxicity or infection, a common concern with live-attenuated and sometimes with inactivated viral vaccines. *In vivo* production of antigens allows for easy access of antigens to both class I and class II major histocompatibility complex (MHC) molecules. As a result, both $CD4^+$ and $CD8^+$ T-cell responses are generated. Although previous generations of vaccines have been largely geared toward eliciting a specific humoral response, vaccine-induced cell-mediated immunity (CMI), consisting of $CD4^+$ and $CD8^+$ T cells, is critical for protection against a variety of pathogens, such as HIV-1 and malaria. A strong T-helper (Th) cell immune response is also critical for the induction of high-quality antibody responses via the induction of antigen-specific B-cell responses.

A series of early studies by Heeney et al. demonstrated a correlation between balanced, vaccine-specific $T_h1$ and $T_h2$ $CD4^+$ T-cell responses and protection against viral challenge in NHPs immunized with recombinant HIV-1 Env gp120 protein vaccines [34–36]. A strong T-helper cell immune response is also critical for the induction of high quality antibody responses via the induction of antigen-specific B-cell responses. Cytotoxic T cells have been correlated with reduced viremia and viral replication in infected NHPs, suggesting their crucial contribution to viral control and protective immunity [37–39]. Because of the very nature and life cycle of *Plasmodium falciparum* malaria, by which the parasite accesses the bloodstream, hepatocytes, and erythrocytes, an ideal vaccine would induce a broad immune humoral and CMI response to provide protective immunity at multiple levels and at each life cycle stage [40]. For both HIV-1 and malaria, DNA vaccine technology provides a unique method by which to induce diverse immune responses required for protective immunity.

In 1992, Tang et al. made an early contribution to the field by immunizing mice with plasmid DNA encoding the human growth hormone (hGH) gene under transcriptional control of either the cytomegalovirus (CMV) promoter or the human β-actin promoter. To confirm the application of this immunization technique to other protein sources, mice were alternatively immunized with DNA plasmid encoding human α 1-antitrypsin under control of the CMV promoter. They used a ballistic gene gun immunization strategy, whereby gold beads coated with target DNA were propelled directly into the skin using a handheld ballistic device, which is described in more detail later in this chapter [41]. Immunized animals developed an antigen-specific humoral response after just one DNA immunization. The primary response can be further augmented by subsequent DNA immunizations. This initial study made important strides in demonstrating the immunogenic potential of DNA vaccines, leading the way to immunization against additional pathogens in small animals.

Almost simultaneously, Fynan et al. demonstrated successful inoculation of mice and chickens with DNA vaccines expressing hemagglutinin (HA) antigen of influenza virus, which led to protection against flu lethal challenge. The study also explored a variety of DNA immunization methods, demonstrating the superiority of intravenous (IV), intramuscular (IM), and mucosal routes as compared with intradermal (ID), intraperitoneal (IP), and subcutaneous (SC) injections [18].

In another early study report, mice receiving IM plasmid DNA vaccine encoding influenza nucleoprotein (NP), an internal and more conserved viral component, developed NP-specific cytotoxic lymphocyte (CTL) responses and elevated NP-specific antibody titers. Antigen-specific activation of both arms of the immune response suggested successful cross-presentation of antigen to both MHC class I and II molecules. Immunized mice were protected against viral challenge and demonstrated accelerated viral clearance of both homologous and heterologous viral strains [20]. The role of CMI was confirmed by the protection of mice from heterologous viral challenge by the adoptive transfer of immunized splenocytes [42]. Together, these studies demonstrated high levels of immunogenicity for DNA vaccines in small animal models.

The utility of DNA vaccination was also demonstrated against other pathogens. A one-time, low-dose DNA immunization of mice and guinea pigs with herpes simplex virus-2 (HSV-2) glycoproteins B or D produced specific neutralizing antibodies (NAb), and animals were protected against viral challenge [43]. Rabbits inoculated with DNA encoding the major capsid protein L1 of human papillomavirus (HPV) via IM injection produced NAb responses specific to conformational viral epitopes, conferring protection against viral challenge [44]. The success of HPV vaccination in a small animals particularly stands out not only because of potential protection against infection in humans but also because of the implication of protection against genital carcinomas, which are sequelae of HPV infection.

DNA vaccination has been studied extensively in the context of HIV-1. IM immunization in mice with DNA plasmid constructs expressing the gp160 form of HIV-1 envelope (Env) produced strong antigen-specific antibodies with neutralizing capabilities, as compared with mice immunized with recombinant gp160 protein. In

addition, immunized mice demonstrated lymphocyte proliferation and a broad spectrum of IgG isotypes in immune sera. Vaccine-induced antibodies prevented Env binding to $CD4^+$ T cells, supporting the concept that DNA immunization generated immunity against conformational epitopes on the target pathogen [10]. The breadth and quality of humoral responses, as well as cross-presentation to both $CD4^+$ and $CD8^+$ T cells, in mice immunized with Env DNA vaccines was confirmed by later studies [45]. Furthermore, strong neutralizing activity was demonstrated even with low anti-Env titers, and immunization of mice with a transgene encoding HIV-1 capsid protein yielded persistent antigen-specific antibody responses [46].

The immunogenicity of HIV-1 Env DNA vaccines in rhesus macaques was also demonstrated, especially with the use of gene gun or electroporation immunization methods. Although specific NAb and CTL responses were elicited, partial protection was achieved even in a highly difficult to protect challenge model using uncloned SIV251 viral stock. Infection was attenuated and viral load was reduced in immunized animals compared with naïve animals [47]. Chimpanzees immunized with DNA encoding HIV-1 antigens Env, Rev, and Gag/Pol also produced vaccine antigen-specific antibody and CTL responses and were protected partially against heterologous challenge [7].

Although several versions of prophylactic, recombinant protein-based vaccines for HBV have been approved for routine clinical use, the presence of 350 million people chronically infected with HBV worldwide suggests a need to develop additional therapeutic vaccines to supplement existing drug treatment, which is unable to achieve full and long-term control in such a population [48]. Along with influenza and HIV-1, HBV was among the earliest pathogens studied in the context of DNA vaccination and the first model pathogen studied in chimpanzees. A rapid, robust, and long-lasting humoral response, including potent NAb, as well as indications of T-helper responses, was elicited in mice receiving IM DNA plasmids encoding hepatitis B surface antigen (HBsAg) [14,15]. The immunogenicity of HBV DNA vaccination was confirmed in chimpanzees [13]. HBsAg-specific antibody titers elicited by DNA immunization in clinical trials with healthy human volunteers reached levels sufficient for human protection [14].

Mice immunized with IM plasmid DNA encoding rabies virus glycoprotein demonstrated a broad, specific immune response of CTLs, helper T cells, and NAb, which protected animals against viral challenge [12]. NHPs have also been successfully vaccinated with DNA encoding rabies virus glycoprotein and protected against lethal challenge [11].

In the early 1990s, the World Health Organization (WHO) used the term "nucleic acid vaccines" as the official name for DNA vaccination, with the consideration that RNA may also be used as the delivery vehicle for a "gene-based" vaccination approach. Indeed, in recent years, there has been active work using RNA as vaccines. A recent study by Geall et al. [49] demonstrated the efficacy of immunization with self-amplifying RNA encoding replication machinery of alpha viruses along with genes encoding alpha virus protein antigens, or respiratory syncytial virus (RSV) F antigen, as an alternative approach to DNA vaccination or viral vector methods. Mice were injected IM with self-amplifying RNAs alone or in conjunction with a

lipid nanoparticle (LNP) delivery system, resulting in the generation of RSV-specific antibody responses. Similarly, immunized rats were protected against RSV challenge, with protection correlating to the induction of RSV-specific IgG and high neutralizing titers, as well as reduced viral load [49]. Additionally, Petsch et al. [50] have demonstrated the application of mRNA vaccination against influenza A infection. Pigs and ferrets were immunized with an mRNA encoding full-length influenza A/PuertoRico/8/1934 HA. Immunization resulted in humoral and CMI, which was cross-protective against multiple antigens. These vaccine-induced immune responses were correlated to protective immunity [50].

In this chapter, the main focus is on DNA vaccines because significantly more experience has been accumulated with DNA vaccines compared with RNA vaccines.

### 17.2.2 Challenges and New Progress of DNA Vaccination in Humans

Human studies of DNA vaccines were started shortly after successful small animal and NHP studies. However, promising protective immunity observed in small animals and NHPs was not observed in human studies when DNA vaccines were used alone. Experience accumulated in the past two decades of clinical studies demonstrated that DNA vaccines had a high safety and tolerability profile, but the overall immunogenicity of DNA vaccines was quite low [51,52]. Initial studies of DNA immunization with HIV-1 Env and Rev in asymptomatic HIV-1–infected patients indicated only low levels of antigen-specific CTL and antibody responses, and no changes in viral load or lymphocyte counts were observed. More importantly, immune responses were not persistent [25]. In contrast, DNA immunization with HA antigen of influenza H1 subtype was able to elicit protective levels of antibody responses in humans [53–55]. This result confirmed what was observed with HBV S DNA vaccines [56]. Interestingly, both flu HA and HBV S proteins are highly immunogenic antigens, and in both studies, a gene gun was used to deliver HA and HBV DNA vaccines; other human studies mainly used traditional needle injection. Overall, low immunogenicity of DNA vaccines in humans has led to attempts to optimize DNA vaccine constructs, formulations, and delivery approaches.

The major novel immunization regimen to emerge in human studies consisted of a prime-boost strategy. This strategy focuses on improved elicitation of both T-cell and humoral immunity in human models. Two general categories of prime boost have been widely studied. A DNA prime followed by a viral vector boost consists of DNA "priming" inoculations followed by a "boost" with a recombinant viral vector expressing antigens homologous to the DNA prime [57,58]. The goal of this approach is to induce strong T-cell immunity. Several viral vectors have been used in preclinical and clinical trials, including vaccinia virus [59–63], adenovirus [64–69], and fowlpox [70]. A clinical study by McConkey et al. in 2003 [60] demonstrated the utility of a DNA prime encoding a *P. falciparum* malaria antigen followed by a boost with replication-defective modified vaccinia Ankara (MVA). The elicited T-cell responses were substantially higher with the prime-boost regimen compared with either component alone, and partial protection, characterized by delayed parasitemia, was conferred [60].

Another approach uses DNA priming followed by boosting with the same antigen in the form of recombinant protein, with the goal of enhanced antigen-specific humoral responses as well as CMI [58,71–73]. This regimen has been extensively examined in the context of HIV-1 vaccination in both preclinical [74–78] and human studies [73]. In a phase I clinical trial, a multiclade HIV-1 Env DNA prime protein boost vaccine regimen demonstrated robust antigen-specific T-cell and broad NAb responses in humans [73].

It is important to note that although DNA priming with subsequent protein boosting is efficacious, simultaneous immunization with matched DNA and protein has an unexpected effect. Recent work from Bin Wang's group demonstrated that mice receiving plasmid DNA encoding a viral antigen together with recombinant protein antigen had reduced antigen-specific effector T-cell responses, as well as induction of suppressor T cells [79]. This effect occurs only when the DNA and protein are matched in targeting the same antigen; this effect was not observed with antigens from different viruses. Also, the authors emphasized that such a "suppressing effect" was not observed for antibody responses. In fact, this immune suppression is antigen-specific, inducing a subset of specific regulatory T cells that is $CD4^{+}CD25^{-}$ and produces Foxp3, interleukin-10 (IL-10), and interferon-γ (IFN-γ) [80]. Although this strategy should be avoided in protective immunization, the induction of antigen-specific immunosuppression may actually be a useful strategy in suppressing undesirable immune responses, as in cases of autoimmune disease and transplant.

The field of DNA vaccination has made substantial strides in the past 2 years, offering a strategy to combat pathogens against which immunity remains elusive. In addition, this new vaccine technology offers a simpler, less expensive alternative to established vaccines. This progress in DNA vaccine research has lead to a vast expanse of clinical trials for vaccines against influenza, HIV-1, malaria, and HPV, as well as potential bioterrorism threats such as anthrax, severe acute respiratory syndrome, and Ebola. In particular, DNA prime-boost strategies have improved responses in human vaccines [81].

## 17.3 DNA PLASMIDS AS A NEW GROUP OF BIOLOGICAL DRUG PRODUCTS

Vaccines are traditionally not classified as drugs because vaccines prevent the establishment of a disease but do not treat well-established or chronic disease. However, the concept of vaccines has been expanded greatly in recent years because "therapeutic vaccines" are being tested to control or cure illnesses. Similarly, the DNA vaccination approach has been explored to achieve either preventive or therapeutic purposes. In addition, the discovery of DNA plasmids as an effective delivery vehicle also raised possibility of further applications using DNA plasmid to deliver cytokines or other biologically active molecules and the utilization of CpG sequences encoded within a DNA plasmid or oligo as an immunologically active adjuvant in the following section, selected examples are presented for all of these applications.

### 17.3.1 DNA Plasmids as Preventative Vaccines

***17.3.1.1 Influenza*** Two types of licensed seasonal influenza vaccines are currently used to immunize humans against infection, both of which are composed of three strains of influenza predicted by the WHO to be in circulation for a particular year. The first, approved for use in all populations, is an inactivated virus vaccine. The second, restricted in children, elderly adults, pregnant women, and other groups, is a live-attenuated viral vaccine. Although existing vaccination strategies protect vaccinees against the predicted subtypes, certain characteristics of influenza present challenges. Influenza strains undergo antigenic shifts as they circulate, altering viral antigens and leading to escape from vaccine-induced immunity. The ease and speed with which DNA vaccines can be produced suggests that seasonally circulating strains may be targeted with greater speed and accuracy by DNA vaccination. In addition, there was hope that DNA vaccination could generate CMI responses that were unaffected by antigenic reassortment. A phase I clinical trial in 2006 demonstrated the immunogenicity of an influenza DNA vaccine using the HA antigen [54]. Volunteers with preexisting low, but positive, titers against HA received gene gun DNA immunization encoding HA from the H3N2 strain A/Panama/2007/99. Vaccinees receiving the highest dose of DNA, 4 μg, produced significant levels of antigen-specific protective antibody responses [54].

In a recent study from the National Institutes of Health's Vaccine Research Center (VRC), volunteers received one (at day 0) or two (at day 0 and week 4) IM H5 DNA immunizations. An H5N1 monovalent inactivated vaccine was subsequently administered at 4 or 24 weeks after the DNA prime immunization. DNA priming followed by an inactivated vaccine boost 24 weeks later yielded protective HA-specific antibody titers in 81% of vaccinees, a fourfold increase compared with individuals receiving only inactivated vaccine. Individuals receiving a prime boost also generated NAb responses. This study demonstrated the benefit of DNA priming in enhancing the efficacy of an inactivated influenza vaccine [82].

***17.3.1.2 Human Immunodeficiency Virus 1*** Recombinant HIV-1 Env gp120 protein vaccines have been studied with minimal success in humans. A phase III clinical trial in high-risk individuals demonstrated that gp120 protein immunization induced a humoral response but failed to impact rate of infection, viral load, and other parameters [5,6]. DNA priming combined with a boost of either viral vector or recombinant protein has been much more efficacious in several human trials.

The EuroVacc02 phase I trial, an international effort, consisted of two IM DNA primes at weeks 0 and 4 followed by two poxvirus vector NYVAC boosts at weeks 20 and 24 [83]. Both constructs contained two HIV-1 antigen inserts derived from a clade C viral isolate, one insert encoding fused Gag, Pol, and Nef, and the other encoding Env gp120. Broad antigen-specific $CD4^+$ and $CD8^+$ T-cell responses were observed in 90% of vaccinees at weeks 26 and 28 at the conclusion of the immunization regimen. These responses were persistent at 72 weeks. In addition, strong anti-Env IgG antibody responses were present in the majority of individuals receiving the full regimen. T-cell and antibody responses were superior in individuals

receiving a prime-boost regimen compared with viral vector alone. However, no NAbs were detected. In addition to demonstrating the ability to elicit a promising immune response against HIV-1, the EuroVacc02 trial also demonstrated the crucial role of DNA priming in eliciting humoral and CMI. Although the lack of NAb activity indicates that additional work is needed, EuroVacc02 has achieved the strongest immunogenicity for T-cell responses in a DNA prime-viral vector boost strategy up to that point [83,84]. Previous trials using a DNA prime with MVA boost have demonstrated much lower antibody and T-cell responses [85].

An HIV-1 DNA prime-protein boost vaccine strategy using a formulation called DP6-001 was the first such regimen to be tested in a phase I clinical trial. Volunteers received three IM or ID DNA vaccinations at weeks 0, 4, and 12 followed by two protein boosts at weeks 20 and 28 [73,81]. DNA immunization consisted of five Env gp120 plasmids from clades A, B, C, and E, as well as one plasmid encoding clade C Gag. Protein boosts consisted of the recombinant Env antigens expressed by the DNA transgene, adjuvanted with QS-21. Although antibody responses were unimpressive at the end of three DNA vaccinations with low-dose DNA prime, after only one protein boost, 100% of volunteers produced high gp120-specific antibody titers ($1 \times 10^4$–$10^5$). Not only were these antibody titers maintained for more than 6 months, but immunized sera also demonstrated broad neutralizing activity against homologous and heterologous viral isolates from genetically diverse strains. In addition, vaccine-elicited T-cell responses were potent and polyfunctional. The DP6-001 trial is a landmark study in part because of the ability of responders to produce broad NAb against multiple subtypes of the HIV-1 virus in addition to balanced humoral and CMI responses.

***17.3.1.3 Malaria*** As a parasite, malaria represents a unique but important target for vaccination, with an estimated 216 million cases of infection in 2010 [86]. Many of the current vaccine strategies are aimed at generating a T-cell response against liver-stage parasites of the *P. falciparum* subtype. In various studies, DNA plasmid encoding *P. falciparum* circumsporozoite protein (PfCSP) was administered either three times at multiple doses via IM [30], or three times at a high dose of 2500 μg via IM or ID using a Biojector [31]. In general, vaccine-induced CMI responses were very low. Although the vaccine formulations were safe, antibody responses were not detectable in any of the vaccinated individuals [29].

DNA prime-MVA viral vector boost strategies have yielded more success in humans. A DNA prime-MVA boost using thrombospondin-related adhesion protein as well as multiple T-cell and B-cell epitopes (ME-TRAP) from *P. falciparum* was evaluated in clinical trials [87]. Volunteers received IM or gene gun DNA vaccination. An additional group received ID boosting with MVA expressing ME-TRAP [60]. Individuals who received the MVA boost immunization produced significantly higher specific T-cell responses than those receiving DNA vaccination alone. The combination prime-boost regimen conferred partial protection manifested as delayed parasitemia after heterologous sporozoite challenge. A subsequent study found that the DNA ME-TRAP prime and MVA-boost was threefold more immunogenic in African volunteers than in volunteers in the United Kingdom [62]. MVA ME-TRAP

boosting also enhanced the immune response of a prime with recombinant fowlpox vector encoding ME-TRAP [61].

***17.3.1.4 Hepatitis B*** Simple DNA vaccination has been remarkably successful in the HBV model. In a milestone study, a DNA plasmid encoding HBsAg as well as an additional antigen, pre-S2 from the strain *adw*, was administered via gene gun at weeks 0, 8, and 16 to naïve volunteers. By the third vaccination, all immunized volunteers produced high antibody titers and strong T-cell responses characterized by both $CD8^+$ T cells and $CD4^+$ T cells with a $T_h1$ bias. Additionally, increased DNA dosage enhanced antibody titers [56]. A subsequent study of DNA vaccination with HBsAg via gene gun was performed in individuals who demonstrated poor responses to conventional HBV vaccination. DNA vaccination produced positive antibody titers in the majority of vaccinees after only one immunization, demonstrating an advantage of DNA vaccination over conventional strategies [88].

### 17.3.2 DNA Plasmids as Therapeutic Vaccines

***17.3.2.1 Chronic Hepatitis B*** The utility of DNA vaccination has been explored in therapeutic as well as prophylactic contexts. Despite an existing HBV vaccine, more than 370 million people worldwide are chronically infected, likely because of poor T-cell activation. In a phase I clinical trial, 10 chronically infected patients who responded poorly to conventional treatment received three IM DNA vaccinations with a plasmid-encoding viral surface proteins. After the well-tolerated immunization method, sera viral loads decreased in most recipients, and patients displayed increased peripheral blood mononuclear cell (PBMC) proliferative capabilities upon stimulation with HBV antigen. In addition, the vaccine elicited antigen-specific T-cell responses in several patients [89,90]. This study suggests an alternative to conventional therapy for patients with chronic infection refractory to treatment.

***17.3.2.2 Human Papillomavirus*** The US Food and Drug Administration (FDA) recently licensed a prophylactic vaccine against HPV and associated cervical cancers. Gardasil (Merck & Co., Inc., Whitehouse Station, NJ) is a virus-like particle-based quadrivalent vaccine against four strains of HPV that result in 70% of cervical cancers, including HPV-16 and HPV-18 [91]. DNA vaccination presents a promising approach for a therapeutic strategy for HPV infection and associated genital dysplasia. In a phase I clinical study, patients received four IM immunizations with ZYC101, which consists of DNA encoding HPV-16 viral protein E7. The highest dose of DNA produced transient resolution in several individuals; however, atypical cells and dysplasia were detected as early as 15 weeks after vaccination. Specific T-cell responses were increased in a few patients, two of whom demonstrated no evidence of virus in the weeks after vaccination [92]. A subsequent study with ZYC101 in patients with high-grade cervical dysplasia showed that patients receiving the middle dosage of 100 μg demonstrated decreased histologic evidence of disease and undetectable viral load. These patients also produced HPV-specific IgA. Overall, immunized individuals exhibited improved antigen-specific

T-cell responses against HPV [93]. A study of ZYC101a, modified vaccine formulation to include viral proteins E6 and E7 from both HPV-16 and HPV-18, found that in immunized women younger than 25 years of age, dysplasia resolution was significantly higher than in untreated groups [94].

***17.3.2.3 Cancer Vaccines*** Generally, tumor-associated antigens are weakly immunogenic, although spontaneous immunity is generated at low levels, which may lead to a beneficial immune response or more destructive tolerance. Passive immunotherapy has been shown to be successful in the treatment of cancer in studies of antibody treatment for B-cell tumors or subsets of breast cancer [95]. DNA vaccination offers a promising strategy to deliver tumor-specific antigens or other immunomodulatory molecules to the immune system to enhance and more specifically target cancerous lesions.

Clinical trials have been performed with the administration of intratumoral Leuvectin (Vical, San Diego, CA), a well-tolerated DNA–lipid complex that encodes human IL-2. In a therapeutic setting for prostate cancer previously unresponsive to treatment, increased T-cell infiltration and lymphocyte proliferation were observed. Two-thirds of patients demonstrated a transient decrease in serum prostate-specific antigen, a marker of disease [96]. Patients with metastatic renal cell carcinoma receiving intratumoral Leuvectin demonstrated increased IL-2 expression and improved CTL tumor infiltration. A small percentage of patients experienced partial responses, and 23% of patients experienced disease stabilization over a median of 8 months after treatment [97].

Another phase I trial used a DNA plasmid encoding tyrosinase in patients with stage IV melanoma administered by four infusions into lymph nodes. Although expression of the plasmid was rarely detectable and no clinical responses were observed, the patients receiving the highest dosage level preferentially demonstrated prolonged survival [98].

Clinical trials have also focused on intratumoral injection of an allogenic MHC class I gene, HLA-B7, formulated in a cationic lipid vector (Allovectin-7, Vical, San Diego, CA). Immunized patients were negative for HLA-B7. Patients with metastatic melanoma received between one and three injections at single lesions at multiple doses at 2-week intervals. Expression of the plasmid was confirmed in 93% of patients, and 50% of patients demonstrated tumor responses in terms of decreased nodule size by more than 25%. However, a number of adverse effects were observed, including hemorrhage and hypotension, indicating the necessity of further study [99]. Treatment was well tolerated in a subsequent study in which patients with metastatic renal cancer receiving intratumoral Allovectin-7 demonstrated increased levels of tumor-infiltrating lymphocytes, and plasmid expression was detected in more than half of immunized patients [100].

One promising application of therapeutic cancer DNA vaccines is the production of patient-specific formulations. B-cell malignancies characteristically express immunoglobulin Id, a tumor-specific antigen that can be recognized by host antibodies as well as T cells. Given the rapidity with which DNA vaccine formulations can be prepared compared with protein formulations, it is feasible to identify and

clone patient-specific variable regions of Id and prepare a corresponding DNA vaccine [101].

In a phase I/II trial, patients with follicular B-cell lymphoma who were in remission after chemotherapy received DNA plasmids encoding the idiotypic variable immunoglobulin chains from each patient's tumor. Patients received three monthly immunizations at a range of doses. Initial results were weak, with no humoral responses detected and minimal evidence of T-cell stimulation. All patients received a second series of IM or ID immunizations via the Biojector injection device, and 50% demonstrated anti-Id humoral and T-cell responses cross-reactive against other patients' tumors. A third series of injections included DNA plasmid-encoding human granulocyte-macrophage colony-stimulating factor (GM-CSF), but this did not substantially boost existing responses [102]. Despite modest antitumor immune responses, DNA vaccines remain a promising candidate for patient-specific immunotherapy.

### 17.3.3 DNA Plasmids as Adjuvants

Clinical trials have demonstrated the unexpectedly weak immunogenicity of naked DNA plasmids delivered IM in humans compared with animal models. As a result, as DNA vaccine technology and clinical studies have progressed, there has been an extensive effort focused on the optimization of DNA formulations, regimens, and delivery methods. Optimization and delivery methods are discussed later, but the development of molecular and genetic adjuvants encoded along with target antigen in DNA plasmids have become an active field of study.

***17.3.3.1 Genetic Adjuvants*** Plasmids encoding cytokines, chemokines, or co-stimulatory molecules may be co-administered with DNA vaccines to enhance or modulate the vaccine-induced response. A range of inflammatory and helper T-cell cytokines have been studied in small animal models in conjunction with DNA vaccination [103,104]; however, a few in particular stand out for their potential in human vaccination.

The $T_h1$ cytokine, IL-2, activates $CD4^+$ and $CD8^+$ T cells, as well as natural killer cells. Co-administration with DNA vaccines has produced enhanced humoral and CMI responses in mice, although the adjuvant effect in NHPs has been less promising [105]. Interestingly, fusing IL-2 to the Fc portion of IgG prolongs the half-life and augments the cellular immune response to an SIV/HIV DNA vaccine, improving protection after challenge [106].

IL-12 and IL-15 have also been successful in adjuvanting DNA vaccines. Small animal studies have demonstrated the ability of IL-12 to drive a $T_h1$ response and activate T cells in the context of DNA vaccines for influenza [107] and HIV-1 [108,109]. Conversely, prostate cancer models in rhesus macaques imply a suppression of humoral responses [110]. Another $T_h1$ cytokine, IL-15, plays a role in the activation and proliferation of $CD8^+$ T cells [111]. In small animals, co-immunization of IL-15 plasmid augments vaccine-specific CMI with a $T_h1$ bias in models of HSV [112], influenza [111], and HIV-1 [113]. Rhesus macaques co-immunized with

IL-15 plasmid and a DNA vaccine against simian human immunodeficiency virus (SHIV) demonstrated improved induction of effector $CD4^+$ and $CD8^+$ T cells, as well as protection from SHIV challenge and more rapidly controlled infection [114]. In addition, co-administration of IL-15 and its receptor, IL-15Rα, has been shown to further augment immune responses [115,116].

The use of GM-CSF in conjunction with DNA vaccination has been more widely studied but also controversial. In mice, co-administration of DNA plasmid encoding GM-CSF enhanced antigen-specific antibody and helper T-cell responses in models of rabies [117], HSV [118], and HIV-1 [108]. However, results were less impressive in NHPs and clinical studies. In one study, patients were immunized with a mixed formulation of five malarial DNA vaccines and plasmid-encoded GM-CSF via IM injection. T-cell responses to MHC class I– and class II–restricted epitopes were examined, and it was found that the GM-CSF adjuvant resulted in a negative effect on class I–restricted T-cell responses, and in fact, none of the volunteers were protected from challenge [119].

GM-CSF has also been studied in the context of DNA vaccines against HIV-1. The GEO-D03 vaccine consists of non-infectious HIV-1 virus-like particles (VLPs) that express in a single transcript gp160 Env, Gag, protease (PR), reverse transcriptase (RT), Tat, and Vpu. The VLP also encodes for human GM-CSF. In NHPs immunized with a GEO-D03 prime followed by an MVA boost, coexpression of GM-CSF in the DNA prime conferred significant improvement in protection against infection compared with priming without GM-CSF. Additionally, DNA immunization with GM-CSF demonstrated improved quality of NAb responses and antibody-dependent cellular toxicity [120].

The study of these and other cytokines in a clinical setting is ongoing and should shed further light on the ability of genetic adjuvants to augment the immunogenicity of DNA vaccines.

***17.3.3.2 Cytidine Polyguanosine Nucleotides*** Bacterial DNA contains unmethylated regions of cytidine polyguanine nucleotides, or CpG motifs, which are recognized by Toll-like receptor 9 (TLR-9). The inclusion of CpG motifs in a plasmid DNA backbone that also encodes a vaccine-targeted antigen has been investigated for its potential inherent adjuvant effect. As a TLR-9 agonist, CpG has a role in inducing proinflammatory cytokines, including IL-12 and type I INFs, leading to activation and priming of CTLs [121]. In mice, antigen-specific immunity was correlated with unmethylated CpG motifs, and methylation of these motifs reduced immunogenicity [122]. TLR-9 activation contributed to, but was not required for, immune response to DNA [123]. Furthermore, in mice, CpG motifs contributed to immunogenicity of DNA priming but not to subsequent boosting [121,124].

Although NHPs have demonstrated successful immunity to HBV after vaccination with CpG oligonucleotides in conjunction with recombinant protein [125], an HBsAg DNA vaccine optimized for CpG content demonstrated poor responses in chimpanzees [126]. A CpG oligonucleotide product, CpG7909 (Coley Pharmaceuticals, Wellesley, MA) was licensed to Pfizer as PF3512676 in 2005, primarily

for use as monotherapy or in combination with chemotherapy drugs in cancer treatment. C7909 was also licensed for study to GlaxoSmithKline in 2002 as VaxImmune and to Chiron Corporation (Novartis, Basel, Switzerland) in 2006. Extensive clinical trials have been undertaken to study the utility of CpG alone or in combination with other agents, most notably in cancer treatment. The utility of optimized CpG motifs in DNA vaccine constructs remains to be fully elucidated in humans.

### 17.3.4 DNA Plasmids as Veterinary Vaccines

Since 2005, four DNA products have been licensed for prophylactic and therapeutic purposes in veterinary medicine. Licensure for veterinary use is an enormous step for DNA technology, further confirming the quality of these strategies in large animals and implicating the potential of these vaccines in human disease. In 2005, the first DNA vaccine for West Nile virus (WNV) was licensed for use in horses. Extensive preclinical work confirmed effective protection and strong NAb titers in mice and horses [127], as well as birds [128], using a single IM injection of recombinant plasmid encoding the premembrane and envelope proteins of WNV. A phase I clinical trial of this vaccine in human volunteers was well tolerated and induced specific T-cell and antibody responses [129].

Almost immediately after the equine vaccine licensure, a DNA vaccine was licensed for farmed Atlantic salmon against infectious hematopoietic necrosis virus (IHNV). The plasmid DNA encoded IHNV glycoprotein produced NAb activity and protected against viral challenge [130]. In immunized fish, both antibody and T-cell responses were stimulated along with the induction of type I IFN [131–133]. This vaccine has particular importance in fish farming, both in terms of reducing animal infection and increasing the quantity and quality of farmed fish.

A therapeutic DNA vaccine for malignant melanoma in dogs was given conditional approval in 2007 and was licensed for veterinary medicine in 2010. The DNA plasmid encodes human tyrosinase, a marker of melanoma. The use of a human antigen allows for the production of antibody responses against dog tyrosinase while avoiding the difficulty of tolerance to a self-antigen. Vaccinated dogs produced a strong humoral response against tumor antigen [134]. In addition, dogs with advanced stage metastatic melanoma demonstrated a clinical response in metastases and improved long-term survival with regression of melanoma [135]. This therapeutic use of DNA constructs, effective in even an advanced stage of disease, suggests a clear path toward the treatment of human disease.

The fourth DNA product, licensed in 2007 for use in swine, is directed towards gene therapy rather than vaccination. A plasmid encoding growth hormone–releasing hormone yields an increase in growth hormone. Pregnant swine received IM injections followed by electroporation, with the goal of increasing the quantity and quality of live piglets in a litter and reducing fetal mortality [136,137]. Although not a model of vaccination applicable to human disease, this is an important demonstration of the efficacy of electroporation and DNA-based gene therapy in a large animal.

## 17.4 OPTIMIZATION OF DNA VACCINES

As discussed, the key issue facing the use of DNA vaccines is their immunogenicity in larger animals and humans. Many gene transfer methods work well *in vitro*, but their *in vivo* efficiency is impaired. DNA vaccination is highly immunogenic in mice and smaller mammals but, to date, has only resulted in low-level immune responses in NHPs and humans [138–140]. The lack of strong cellular and humoral responses has hindered the development of DNA vaccines. Fortunately, DNA vaccine plasmids are easily manipulated, providing many possibilities for increasing antigen expression and immunogenicity. Several methods exist for optimizing plasmid transcriptional elements and protein production. The goal of this section is to discuss the factors that affect DNA vaccine efficacy and how they may be altered to improve the immune response.

### 17.4.1 Optimization of Transcription

The use of a plasmid backbone offers many advantages with regard to optimization. Much work has been done to identify methods that increase both gene transcription and protein expression. Of particular interest is the gene promoter. Initial studies established that microbial promoters are poor inducers of mammalian gene expression. Early research focused on oncogenic, virally derived promoters. The first promoter to be investigated was the simian virus 40 (SV40) promoter [141,142]. The SV40 promoter was used until researchers identified the Rous sarcoma virus promoter as having the capacity to drive higher transgene expression rates [141]. These promoters were effective, but some concern existed because of their link to cancer.

Later, noncarcinogenic sources garnered interest. The most common choice is the human CMV immediate early promoter because it yields the highest level of transgene expression. A comparison of the CMV immediate early promoter to a plasmid containing the endogenous AKV murine leukemia long terminal repeat (LTR) demonstrated that the CMV plasmid elicited higher antigen-specific responses [143]. The CMV promoter also offers two additional advantages. It provides for constitutive expression of the transgene within a wide range of mammalian cells, and it does not suffer from downstream read-through, preventing transcription of the plasmid backbone. In general, virus-derived promoters provide for greater transgene expression *in vivo* than do eukaryotic promoters.

In addition to the use of a strong viral promoter, several other transcriptional elements may be inserted into the plasmid open reading frame to enhance promoter activity. Similar to the previously mentioned promoters, many transactivator genes are derived from viral enhancer regions. The inclusion of transcriptional enhancers and transactivators, such as the CMV intron A and LTRs, have been shown to boost the antigen-specific response above levels seen with the CMV promoter alone [144,145]. It is believed that the inclusion of Intron A enhances the rate of polyadenylation and nuclear transport of mRNA [146]. Inclusion of strong promoters or enhancers increases the rate of transcriptional initiation [146,147].

Another factor affecting plasmid expression is the efficiency of primary RNA transcript processing and polyadenylation. Polyadenylation sequences have varying efficiency with regard to primary RNA transcript processing, significantly affecting transgene expression. For example, the SV40 polyadenylation sequence is less efficient than bovine growth hormone polyadenylation sequences when expressed in mouse liver. This may be rectified by the addition of a second SV40 enhancer downstream of the original SV40 polyadenylation signal [148].

### 17.4.2 Enhancing Protein Production

*In vivo* protein expression is required for DNA vaccine efficacy. Consequently, improved expression of the transgene antigen is expected to boost the immune response. Codon optimization is a highly effective strategy for increasing protein production [149–151]. Numerous organisms have biases in their codon usage. This discrepancy exists because transfer RNAs (tRNAs) are not at equal levels within all cells. Consequently, certain codons are negatively selected in particular cell lines. The use of an antigenic codon sequence that uses more abundant tRNAs increases translation efficiency, resulting in increased antigen expression and a higher antigenic dose. Increased antigenic protein expression leads to enhanced CTL and humoral responses.

Another common method of improving transgene expression is the optimization of the start site for protein synthesis. The sequences surrounding the mRNA start codon impact its recognition by eukaryotic ribosomes. Many expression vectors carry modified Kozak consensus sequences ($^{-6}$GCCA/GCCAUGG$^{4+}$) that allow for optimal expression in mammalian cells [152]. Not all eukaryotic genes possess Kozak sequences; therefore, inclusion in the plasmid may augment expression levels. There is a major caveat to increased protein synthesis because it is necessary to ensure translation terminates, preventing read through of the bacterial genome. As such, many plasmid constructs encode extended poly A tails and double stop-codons. These modifications help stabilize mRNA and function to disrupt ribosome–mRNA interactions.

Finally, the inclusion of a leader sequence can add another dimension to plasmid optimization. Leader sequences can enhance the stability of mRNA and increase the efficiency of translation. Many native leader sequences found on antigenic proteins hinder cleavage and lower the rate of folding inside the endoplasmic reticulum [148,153]. To counteract this problem, the human tissue plasminogen activator (tPA) has become a standard inclusion in plasmid design. Human tPA inclusion results in a marked increase in protein expression and immunogenicity [148,154].

### 17.4.3 Delivery of DNA Vaccines

As discussed, the goal of DNA immunization is to transfect host cells, allowing for both MHC class I and II antigen presentation. Therefore, it is not surprising that the method and route of immunization have significant effects on DNA vaccine efficacy.

Although a wide range of delivery approaches are currently being investigated for DNA vaccines, they can be divided into two groups. The "chemical delivery" approaches share the common features of a liquid formulation, but the facilitating reagents vary. In contrast, the "physical delivery" approaches take advantage of a particular physical force (such as air pressure or electrical pulse) to deliver the DNA plasmids into targeted tissues or cells. This section discusses the benefits and drawbacks of each delivery route and addresses possible methods for increasing their effectiveness.

***17.4.3.1 Chemical Delivery Methods*** Several chemical formulations have been used to boost DNA vaccine efficacy. The most basic and commonly used approach simply involves IM injection of vaccine plasmid diluted in phosphate buffered saline (PBS) or saline. The benefit of this approach is that it does not require additional manipulations before vaccine administration. Unfortunately, because plasmid-based vaccines rely on endocytosis and pinocytosis for transfection, much of the injected DNA is wasted. Exogenous DNA either diffuses away or is degraded in the extracellular space. This has resulted in the need to significantly increase the amount of plasmid DNA required for cell transfection. Human trials have required doses of plasmid DNA in the range of 500 to 2500 μg [30,73].

To this end, several laboratories have developed chemical methods that not only enhance transfection efficiency but also have an adjuvant effect. The use of liposomes as carrier molecules has recently become a popular delivery method. One formulation that has shown a clear benefit in human trials is Vaxfectin (Vical, San Diego, CA). Vaxfectin is a proprietary formulation of cationic lipid (GAP-DMORIE) and a neutral phospholipid (DPyPE) that self-assembles into liposomes when mixed. IM injection of a Vaxfectin–influenza NP mix increased antibody titers 20-fold compared with vaccine alone [155,156]. Boosting of antibody titers did not result in a diminished cytotoxic T-cell response. Likewise, inclusion of Vaxfectin in a *P. falciparum* vaccine enhanced the IFN-γ production [157]. An ensuing human trial involving DNA plasmids formulated against the influenza H5 HA, NP, and M2 genes reported response rates and antibody titers in the range of inactivated protein-based H5 vaccines [158].

The other development in DNA vaccine formulation is the use of biodegradable polymeric microparticles as a carrier system, thereby protecting the vaccine plasmid from extracellular deoxyribonucleases. Microspheres, consisting of amphiphilic molecules, have proven especially efficient at delivering DNA to cells. In addition to protecting plasmid DNA from nucleases, microspheres promote the sustained release of vaccine without repeat dosing. High-molecular-weight cationic polymers have proven even more effective than cationic liposomes in aggregating DNA. Plasmid DNA immobilized within the biodegradable polymeric microspheres (chitosan-coated alginate microspheres with diameters ranging from 20 to 500 μm) can induce both systemic and mucosal immune responses [159]. Microspheres may be delivered orally or intraperitoneally, where they can transfect dendritic cells, yielding higher levels of dendritic cell activation. The benefits of such formulations have been shown in mice, NHPs, and humans [160–164]. These results suggest that

microparticle-based delivery systems are capable of enhancing DNA vaccine immunogenicity and boosting cellular and humoral immunity.

***17.4.3.2 Physical Delivery Methods*** Different from the chemical delivery approaches, the physical delivery approaches use different kinds of external physical means to "force" the delivery of DNA vaccine plasmids.

As previously mentioned, the most common route of DNA immunization is IM injection of DNA diluted in saline, which has the benefit of requiring no special delivery system and can be delivered without specific tools or instruments. A similar method is ID injection, in which DNA plasmid is delivered between the layers of skin. Both IM and ID injection have been demonstrated to be $T_h1$ biased, favoring a strong CTL-based response. Notably, it has been demonstrated that the direct transfection of antigen-presenting cells (APCs) is key to successful immunization [165,166]. This has led to the use of transcutaneous microneedle injectors that bypass the upper stratum corneum skin layer and deliver the vaccine to an area rich in APCs, particularly Langerhans cells. Likewise, subsequent boosting immunizations may be delivered to increase cellular and humoral responses. At the same time, more sophisticated instruments have been developed to improve the transfection efficiency of DNA immunization.

Electroporation has long been used *in vitro* to increase transfection efficiency. The application of an electrical pulse to cells temporarily opens pores in the lipid bilayer, allowing DNA to traverse the cellular membrane down the concentration gradient. Subsequent analysis proved that electroporation also functions *in vivo* with minimal cell damage. Naked plasmid is injected into the tissue, and an electric pulse is applied via needle or caliper-type electrodes. This has the added benefit of recruiting inflammatory cells to the site of injection. Electroporation has been shown to increase gene expression up to 1000-fold compared with animals receiving only IM injection. Additionally, electroporation may be applied to many tissue and cell types [167].

Another technique involves propelling DNA plasmid-coated gold beads into the skin using a gene gun. The Helios gene gun (Bio-Rad Laboratories, Irvine, CA) uses high-pressure, helium gas-powered particle bombardment to directly transfect target cells or tissues. This method was initially shown to be capable of generating immune responses in reporter mice [41]. Human clinical trials involving hepatitis B transgenes have established that gene gun immunization is capable of inducing protective immunity in humans [56,88]. Several differences exist between IM and gene gun immunization. Reports have shown that significantly less plasmid DNA is required for generating protective immunity by gene gun immunization in mice [18,73]. The direct transfection of target cells also favors a $T_h2$ immune response, as opposed to the $T_h1$ bias of IM injection. It is a potentially important issue that only a small amount of DNA can be coated onto the gold beads. However, at this point, the main reason to prevent wide use of this technology is the limited access of this technology because of intellectual property rights ownership.

Other needle-free injection systems have been investigated. So-called pneumatic or jet injectors have shown promise in both animal and human clinical trials

[28,168–172]. Jet injectors function by injecting a high-pressure, narrow stream of injection liquid into the epidermis of patients. Similar to the gene gun, it is powered by compressed air or gas. These devices are capable of delivering medication via the IM, ID, or SC routes. Several studies have demonstrated enhanced immune responses compared with needle and syringe delivery. The major concern with previous needle-free injection systems was the possibility of disease transmission between patients. Because the jet injector breaks the skin barrier, there is a small, but measurable, chance that biological material may be transferred between users [173]. Current model designs have rectified this by using single-use syringes, thereby eliminating the potential for cross-contamination. Improvements in functionality and safety of jet injectors will make them a strong candidate for use in mass vaccination.

## 17.5 UNPROVEN SAFETY CONCERNS

Traditional vaccines rely on the injection of live-attenuated virus, inactivated viral particles, or recombinant proteins to induce immunity. Inactivated particles and recombinant proteins tend to yield a decreased CTL-based response. Live-attenuated vaccines carry some risk of infection. For example, live-attenuated vaccines have a small possibility of reverting to a pathogenic form and may cause disease in immunocompromised patients. Conversely, DNA vaccines have little opportunity to cause disease because they are often constructed with several safety features. Because DNA vaccine plasmids are nonlive, nonreplicating constructs, there is little risk of pathogenesis. In addition, fears of adventitial agents being transferred from tissue culture lines are bypassed. Likewise, they do not require the use of toxic treatments to inactivate infectious particles, as do killed vaccines. These factors have established DNA vaccines as intrinsically safer than conventional vaccination methods. This section discusses possible safety concerns and describes the fact that no safety concern has been experimentally observed.

### 17.5.1 Integration into Host Genome

The possibility for integration of plasmid DNA into the recipient's genome has been a major focus in early days of DNA vaccine discovery. Integration of plasmid genes could occur either randomly or through homologous recombination, leading to activation of oncogenes, the inactivation of tumor suppressor genes, or mutational shifts in chromosomal DNA. To combat this possibility, several laboratories use suicide vectors that induce cellular apoptosis in transfected cells. This ensures that any integration events are not carried through vertical transmission.

Initial integration studies were undertaken with plasmids encoding either influenza or HIV genes [174,175]. Only extrachromosomal plasmid DNA was detectable after IM injection, suggesting that random integration occurred at extremely low frequencies, fewer than one to eight copies in 150,000 nuclei. Further studies involving plasmid DNA expressing *P. falciparum* circumsporozoite protein (*Pf*CSP) demonstrated similarly low levels of integration [176]. Several groups have

investigated the role of route of immunization in plasmid integration. Upon IM injection, early time points established a low level of systemic plasmid DNA that dissipated quickly. Plasmid was occasionally detected in the reproductive organs (ovaries and testes); however, all DNA was extrachromosomal, leaving little risk for germline transmission [78,175]. Because such frequencies are three orders of magnitude lower than the spontaneous mutation rate of gene-inactivating mutations, many researchers believe that the risk of mutation associated with plasmid integration is negligible.

In contradiction to these studies, one report by Wang et al. was able to identify four independent integration events after electroporation of mice immunized with a plasmid encoding the mouse erythropoietin gene [177]. Wang et al. used repeat-anchored integration capture (RAIC) polymerase chain reaction to detect covalent junctions of plasmid–genomic DNA sequences. Their study demonstrated that electroporation markedly increased plasmid tissue levels. The integration sites appeared to be random, with only short sequences of homology. These studies identify integration events as a possible area of concern despite their low level of frequency. None of these issues have been reproduced by others in preclinical or clinical trials; however, current techniques are not refined enough to conclusively identify the number of integrations associated with DNA vaccination. Further monitoring in clinical studies may help to clarify any negative effects that plasmid integration may generate.

### 17.5.2 Autoimmune Responses

The second major concern raised regarding DNA vaccination is the induction of autoimmunity. The native immunostimulatory nature of DNA plasmids has led to some concern that anti-DNA immune responses may develop. In particular, the ability of unmethylated CpG to activate innate immunity pathways has led to such questions [178]. Investigation of the ability of CpG motifs to induce autoimmunity in mice demonstrated that the production of anti-DNA antibodies was not significantly increased above spontaneous rates [179,180]. Similarly, many plasmids have other immunomodulatory molecules inserted to boost the immune response. The inclusion of cytokine-encoding transgene sequences may result in systemic activation of APCs and T cells. In addition, there is some concern about the inclusion of tPA leader sequences. Some researchers have expressed trepidation that the attachment of a human leader sequence may direct the formation of antibodies against recipient DNA.

It has been demonstrated in rabbits that the inclusion of certain transgene sequences may increase the risk of anti-DNA humoral responses. Low-level, transient antibody responses were seen in animals immunized with a vaccine encoding the HIV-1 RT and HIV-1 nef genes. The authors suggest that these responses were the result of protein–nucleic acid complexes, but there is no evidence to suggest that such responses are the same as in real clinical autoimmune diseases because no positive laboratory biomarkers have been reported [181]. A clinical study performed in humans demonstrated the possibility of mild reactogenicity in the DNA

prime-protein boost vaccination model when a potent adjuvant is used [182]. Superficial skin tissue–based vasculitis developed in two vaccinees receiving three HIV-1 Env DNA primes followed by one Env protein boost adjuvanted by QS-21. The rapid increase in antibody responses after the first protein boost suggests that DNA priming resulted in a strong humoral response, possibly because of increased cytokine production induced by the adjuvant.

To date, there is no convincing evidence that DNA vaccination induces systemic autoimmune disease. Preclinical studies in NHPs and early human trials have not produced any detectable increases in anti-DNA or antinuclear antibodies. Some evidence of reactogenicity in DNA prime-protein boost models has been seen, but this may be attributable to the inclusion of a strong adjuvant or high immunogenicity when DNA is used to prime the immune responses. In summary, there is no solid evidence that DNA vaccines may direct the formation of anti-DNA antibodies at reproducible or detectable levels.

## 17.6 MANUFACTURING PROCESS

DNA vaccination offers a new and credible way to treat humans and animals. As DNA vaccines become more widespread, new methods for optimizing the manufacturing process are in development. Two major issues facing vaccine manufacturers are the quantity and quality of DNA preparations. Quantity issues focus on the ability to produce the kilogram quantities of plasmid DNA required for mass immunization. The old methods of small-scale production are no longer viable because of the increasing demand for effective vaccines. Equally important is the need to increase product purity to meet the specifications of regulatory agencies. Before developing a manufacturing protocol, it is recommended that a critical evaluation of the vaccine plasmid and production be undertaken.

### 17.6.1 Composition of Vaccine Elements

Although plasmid DNA is generally produced in *Escherichia coli*, several *in vitro* production methods have also been investigated. *In vitro* DNA production can generate high plasmid yield; however, these methods require costly and specialized equipment and reagents. Therefore, the majority of production facilities still use large-scale bioreactors. The generation and purification of plasmid DNA presents unique challenges because of its similarity to host cell nucleic acids. Several factors in the plasmid design affect DNA yield. This section reviews these factors and addresses possible courses of action.

Plasmid DNA conformation greatly affects product yield. Proper plasmid conformation is crucial for efficient production. Optimal production requires high levels of supercoiled plasmid because it is believed that supercoiled DNA is therapeutically more effective than are the open-circle, linear, and nicked forms of DNA. Unfortunately, the undesirable forms are difficult to separate from supercoiled

product. In addition, the amount of supercoiled DNA can be decreased by the inclusion of particular gene sequences. Such sequences result in a large percentage of the total plasmid remaining in the open, circular form. Therefore, it is necessary to optimize the plasmid conformation before beginning production.

Plasmid stability is another important factor in manufacturing. Certain sequences decrease plasmid stability. For instance, palindromic sequences and inverted repeats are extremely unstable, but adenosine-thymidine rich regions render the plasmid susceptible to endonuclease nicking. Alternating regions of pyrimidine and purine sequences can be unstable in large batch fermentations [183]. Oligopyrimidine and oligopurine sequences can increase dimer formation [184]. Of particular importance are long regions of CpG repeat sequences [185]. Because these regions are beneficial in generating an innate immune response, a comprehensive investigation of sequence stability is required. Optimal plasmid DNA production may require a reduction in immunostimulatory ligands to reach full production capacity.

Component orientation also affects plasmid function. Many prokaryotic gene sequences negatively affect eukaryotic gene expression [186]. Other prokaryotic genes can bind eukaryotic transcription factors, further inhibiting gene expression [187]. Inclusion of selective marker genes can also limit production yields. It has been demonstrated that CMV promoter expression can be dramatically lowered if inserted in an improper orientation [188]. These factors must be accounted for during the plasmid design phase to ensure that high production levels are met.

### 17.6.2 Fermentation

Two goals are key in designing a fermentation process: high volumetric yield and high concentrations of supercoiled plasmid. Optimal fermentation plans have a small, economical volume that does not waste media or cells. Three strategies are favored in the mass production of DNA plasmids: batch fermentation, fed-batch fermentation, and continuous fermentation. Each process will be examined in turn.

***17.6.2.1 Batch Fermentation*** The simplest method of culturing requires the addition of all nutrients necessary for cell growth at the time of inoculation. Because all nutrients are present immediately after inoculation, the growth rate will remain essentially static. However, as it is sometimes necessary to reduce the growth rate to obtain optimal plasmid production, the growing temperature may be lowered depending on the type of media used [189].

***17.6.2.2 Fed-Batch Fermentation*** The most efficient—and therefore common—method of fermentation involves adjusting nutrient concentrations during cultivation. Limiting amounts of nutrients are added throughout cultivation so as to control growth rate. This method has the added benefit of yielding higher biomass because nutrients are almost completely consumed, precluding the possibility of reaching inhibitory substrate concentrations. Several established fed-batch fermentation protocols are in use today.

*Merck Process* The Merck Process (WO2005078115) involves selecting for highly productive clonal subtypes of the transformed *E. coli* [190]. Transformed *E. coli* are cultivated and selected for on blood agar and chemically defined agar plates.

*Boehringer Ingelheim Process* The Boehringer Ingelheim Process (WO2005097990) uses exponential feeding for the fed-batch phase to sustain biomass growth [191]. Then feeding is switched to a linear constant program to lower specific growth rates and increase plasmid accumulation. Use of the JM108 strain of *E. coli* (WO2005098002) results in high plasmid yields and increased supercoiled plasmid concentrations [192].

*Nature Technology Corporation Process* The Nature Technology Corporation Process (WO2006023546) involves reduced temperatures during the fed-batch phase [193]. This serves to limit the growth rate and maintain plasmid stability while the biomass grows efficiently. The temperature is then increased, and additional nutrients are added. Plasmid yields increase considerably after the temperature shift. Surprisingly, cells are able to tolerate significantly higher quantities of plasmid after the temperature shift.

***17.6.2.3 Continuous Fermentation*** The third cultivation method involves harvesting cells and adding nutrients concurrently. As sterile nutrients are added to the bioreactor, an equivalent amount of converted nutrient solution is removed. This results in some of the microorganisms also being removed. Under steady state conditions, cell loss caused by overflow must be balanced by bacterial outgrowth.

### 17.6.3 Purification

Large-scale production of plasmid DNA presents many challenges that must be considered before production begins. Several issues also exist in the downstream processing of plasmid DNA. The goal of the purification process is to remove all impurities from the cell lysates, leaving only highly purified plasmid DNA. Purification methods are difficult and expensive but are necessary for producing a safe, clinical-grade product. The majority of manufacturing costs occur during the purification phase, primarily because of the difficulty of separating plasmid DNA from host cell DNA and the relatively small amount of plasmid DNA produced from a fermentation batch. The type of plasmid used in fermentation is a key aspect in designing a purification process.

Before beginning any purification, it is critical that any purity requirements be identified. Commercial plasmid products generally have lower quality needs than do vaccine-related products. The chief impurities in any plasmid DNA preparation are chromosomal DNA, protein, RNA, and endotoxins that may be present in *E. coli*. These impurities may be removed through several methods, including nuclease treatment, chromatography, selective precipitation, and tangential flow filtration. It is often desirable to use more than one purification method at each step. For example, both triple helix chromatography and hydrophobic interaction chromatography may be used to remove genomic DNA. Unfortunately, this process is not ideal because many

chromatography columns have poor binding capacity for plasmid DNA, lowering the overall yield. Conversely, high-capacity ion exchange columns have poor binding capacity for genomic DNA. Therefore, it is best to limit the number of purification steps to those absolutely required to meet preestablished purity requirements.

### 17.6.4 Bulk Plasmid Product Release Testing

Testing of bulk plasmid preparations should include plasmid concentration and conformation species identification. As discussed previously, it is recommended that all preparations contain high levels of supercoiled DNA to increase immunogenicity. Similarly, an examination of bulk plasmid preparations should include testing for bacterial host cell contaminants, including RNA, DNA, and protein (<1%). These scales are not strict rules because it is anticipated that contaminant levels will diminish as the development program moves forward. The FDA also recommends Limulus Amebocyte Lysate testing to quantify the presence of bacterial endotoxins within the preparation. Endotoxin levels should not exceed 40 EU/mg of plasmid. In general, the FDA suggests that producers of DNA vaccines establish strict acceptance criteria and that each vaccine lot be tested for compliance.

## 17.7 REGULATORY CONSIDERATIONS

This section is prepared only as a general introduction to the clinical testing of DNA vaccines. Regulatory agencies or experts with experience in updated regulatory requirements should be consulted for such studies.

The US FDA defines DNA vaccines as purified plasmid preparations containing one or more DNA sequences capable of inducing or promoting an immune response against a pathogen [194]. DNA vaccines are considered biological products as described in Section 351 of the Public Health Service Act (PHS ACT) (42 U.S.C.262) and are regulated by the Center for Biologics Evaluation and Research (CBER). Many of the following issues are included in the points of consideration.

The FDA recommends that a summary of all components used during manufacturing be included in the final product application. This includes plasmid construction, intermediate recombinant cloning procedures, and plasmid sequencing. It is also suggested that the genotype of source bacterial cells be described. In particular, analysis of the master cell bank and working cell banks should be included to ensure that products are free of contaminants. Overall, the manufacturing process should be described sufficiently so as to allow for a detailed and clear understanding of the product's safety.

### 17.7.1 Preclinical Immunogenicity and Safety

The FDA requires that all new vaccines be subjected to preclinical safety testing (21 CFR 312.23(a)(8)). All good laboratory practice (GLP) regulations (21 CFR Part 58)

should be applied to production batches intended for clinical use. GLP regulations also apply to any nonclinical studies that are designed to support investigational new drugs (INDs) and biological license applications. Also, preclinical safety studies should be applied to every DNA vaccine–adjuvant formulation under consideration. It is strongly recommended that CBER be consulted before submission of any INDs to ensure that proper preclinical safety studies were completed.

Evaluations of immunogenicity and reactogenicity should be designed to assess any systemic toxicity. Such studies should be done in a relevant animal model to ensure that antigen-specific humoral and CMI responses are within acceptable levels so as to prevent autoimmunity. Preclinical immunogenicity studies are not subject to GLP guidelines unless they are also being used as safety studies. When a persistent immune response is generated against endogenous or self-antigens, it is recommended that any potential adverse effects be studied in a relevant animal model. Such responses should also be monitored in any future clinical trials.

## 17.8 SUMMARY

The use of safe and effective vaccines has become a fundamental aspect of global health. To this end, immunization with a nucleic acid–based vaccine has led to new considerations in vaccination strategies. At least in preclinical studies, antigen-encoding DNA plasmids are capable of eliciting a broad spectrum of immune responses against antigens from a variety of pathogens.

Although DNA vaccination provides several advantages over other established vaccination strategies, further optimization is necessary before it becomes the predominant strategy in human patients. DNA vaccination has shown great promise in prime-boost strategies and may provide a solution for pathogens that were previously thought unpreventable or untreatable. Their adaptability and ease of manipulation may prove to be the aspect that pushes them to the front line of vaccination. It appears that DNA vaccines are on the precipice of redefining the field of vaccinology.

# Multifunctional Polymeric Nanosystems for RNA Interference Therapy

ARUN IYER, SHANTHI GANESH, QIONG L. ZHOU, and MANSOOR AMIJI

## 18.1 INTRODUCTION

RNA-interference (RNAi) is one of the most powerful tools for selective silencing of specific aberrant genes for therapeutic management of diseases such as cancer, diabetes, and inflammatory disorders. However, the labile nature of nucleic acid constructs coupled with the difficulty in selectively delivering them to the target tissues, cells, and the intracellular cellular machinery within the cells has been a primary hindrance for the clinical translation of RNAi. Multifunctional nanosystems provide distinct advantages over other delivery strategies based on their ability to selectively target diseased tissues, such as solid tumors, based on passive and active targeting principles. Such nanosystems can incorporate multiple therapeutic payloads, such as small molecule drugs, small interfering RNAs (siRNA), and microRNAs (miRNA) as well as imaging and contrast agents for simultaneous disease detection, quantifying siRNA and miRNA gene expression and knockdown, examining *in vivo* fate and sites of localization and excretion, and exploring therapeutic potentials *in vivo*. This chapter describes the principles and mechanisms based on the RNAi phenomenon and the barriers to its successful clinical translation. Furthermore, the chapter discusses the modes of delivery that have been used, including the advantages of multifunctional polymeric nano-systems with illustrative examples covering their use in the management of diseases such as cancer, inflammation, and other chronic diseases.

## 18.2 RNA INTERFERENCE THERAPY

### 18.2.1 Principles and Mechanism of Gene Silencing

Gene silencing is a mechanism by which cells can switch off gene expression and therefore prevent protein production. Gene silencing can occur either at the transcriptional or posttranscriptional level. For posttranscriptional gene silencing, the mRNA of particular gene is blocked or degraded commonly by a mechanism called RNAi (Fig. 18.1). The RNAi phenomenon was discovered in 1998 by Andrew Fire and Craig Mello [1], who were awarded the Nobel Prize in 2006. RNAi depends on two small ribonucleic acid molecules, siRNA and miRNA. siRNAs consist of 21-base pair double-stranded RNAs that are generated from long double-stranded RNAs on their cleavage by an RNase III enzyme called Dicer [2,3]. Each siRNA is then separated into single strands, and the antisense strand of the double-stranded RNA is incorporated into the RNA-induced silencing complex (RISC) [4–6] that binds to a complementary sequence of an mRNA molecule. The RNAi (mRNA cleavage) in cytoplasm is induced by Argonaute proteins [7,8], a catalytic component of the RISC complex. miRNAs are 21- to 23-nucleotide-long RNAs and transcribed from their own genes by RNA polymerase II. A miRNA is expressed from a long RNA-coding gene as a primary transcript known as pri-miRNA, which is cleaved by the RNase III enzyme, Drosha [9] to a 65-nucleotide stem-loop structure called pre-miRNA. The pre-miRNA is then exported from the cell nucleus into the cytoplasm, where its loop is removed by Dicer. The mature miRNAs are produced and integrated into RISC. Thus, miRNAs and siRNAs share the same cellular machinery downstream of their initial processing [10]. Binding of a miRNA–Argonaute protein complex to the seed region of 3′ untranslated region (UTR) of an mRNA silences its expression [11]. Most miRNAs trigger general degradation of the target mRNA [12]. In some cases, the miRNA may block the translation of the mRNA into protein [13]. The human gene contains more than 500 miRNAs and each miRNA can repress hundreds of genes, regulating almost every cellular process [11].

### 18.2.2 Small Interfering RNA and Micro RNA as Therapeutic Agents

RNAi can also be activated exogenously by introducing synthetic siRNAs and miRNAs directly into the cytoplasm of cells of interest. The selective and robust effect of siRNA on gene expression makes it an invaluable research tool for functional genomics and as a potential therapeutic agent. siRNA has the ability to knock down or silence virtually any human gene, which greatly expands the number of therapeutic targets that can be explored compared with small molecules. Thus, siRNA can be applied for diseases caused by abnormal gene overexpression or mutation, such as cancer and diabetes treatment.

Aberrant miRNA expression has been linked to many diseases (e.g., the let-7 miRNA prevents proliferation of cancer stem cells [14], but miRNA 143 promotes differentiation of adipocytes) [15,16]. miR 375 regulates insulin secretion in pancreatic islet cells [17], miRNA 122 participates in liver disease [18,19], and miRNA 103/107 is overexpressed in liver biopsies from patients with alcoholic liver

**FIGURE 18.1** Mechanism of RNA interference (RNAi)-mediated gene silencing. AGO2: Argonaute RISC catalytic component 2; DCP1/2: mRNA-degrading enzymes; PACT: protein activator of the interferon-induced protein kinase; RISC: RNA-induced silencing complex; TRPB: typtophan synthase beta subunit; UTR: untranslated region. (Reprinted with permission from Ref. [135].)

disease and nonalcoholic fatty liver disease [20]. Thus, miRNAs and their mimics and inhibitors have great potentials as therapeutic agents.

Together, RNAi represents an important therapeutic strategy. Clinical trials with siRNAs are already in progress [21]. However, the widespread use of siRNAs, miRNAs, and their inhibitors as therapeutic agents for disease prevention and treatment requires the development of safe and effective delivery vehicles.

### 18.2.3 Challenges in Systemic Delivery of RNA-Interference Therapeutics

Systemic delivery of RNAi therapeutics to the targeted tissue and cells has been proven challenging and has many barriers. Intravascular barriers include engulfment of naked siRNAs by macrophages or degradation by serum nucleases [22]. Extracellular nanoparticles, on the other hand, encounter degradation by immune cells and extracellular matrix (ECM). Particles that escape these barriers preferentially traffic to tumors by the enhanced permeability and retention (EPR) effect (Figs. 18.2 and 18.3).

**FIGURE 18.2** Biological barriers of RNA-interference (RNAi) delivery. ECM: extracellular matrix; PEG: polyethylene glycol; RISC: RNA-induced silencing complex. (Reprinted with permission from Ref. [136].)

**FIGURE 18.3** Passive and active drug targeting. The schematic shows the passive and active targeting mechanisms of multifunctional nanoparticles and the difference in the vasculature of normal and tumor tissues; drugs and genes diffuse freely in and out of the normal and tumor blood vessels because of their small size, and thus the effective drug concentration in the tumor falls rapidly with time. However, macromolecular drugs and nanoparticles can passively target tumors because of the leaky vasculature or the enhanced permeability and retention (EPR) effect. However, they cannot diffuse back into the bloodstream because of their large size, leading to enhanced tumor accumulation and retention. Targeting ligands such as antibodies or peptides decorated on the surface of nanoparticles can selectively bind to cell surface receptors or antigens overexpressed by tumor or target cells and can be taken up by receptor-mediated endocytosis (active targeting). After being internalized, the drugs and small interfering RNAs (siRNAs) released from the nanoparticles within the cells can exert the necessary action.

Naked siRNAs with large molecular weight (~13 kDa) and net negative charge can neither readily enter the cells nor easily escape from the lumen of intracellular membranes. Even with direct injection into a targeted site, such as the vitreous humor of the eye, or inhalation directly into the lung, siRNAs must evade nuclease activities, penetrate the interstitial space of cell matrices, cross cell plasma membranes, escape from endosomes, and then load into the RISC complex within the cell cytoplasm to be effective [23]. Another problem is that double-stranded RNAs induce undesirable side effects, such as an inflammatory response. Thus, unprotected and unmodified native siRNA have not been used for gene silencing in directed *in vivo* applications.

Current delivery systems can be categorized into physical methods, conjugation methods, and viral and nonviral carrier-mediated methods. Physical techniques can enhance siRNA uptake at a specific tissue site by pressure or mechanical measures. Terminal-modified siRNAs can enhance their resistance to nucleases in serum and

tissue, and modification with a suitable ligand can achieve targeted delivery [21]. Nonviral carrier systems include nanoparticles, liposomes, lipoplex, polyplex, and receptor-targeted nanocomplex. These nonviral systems have shown improved siRNA encapsulation, delivery to targeted tissue, and more effective silencing with less cellular toxicity and immune responses.

This chapter illustrates in detail viral and nonviral delivery systems with an emphasis on multifunctional polymeric nanosystems for siRNA delivery.

## 18.3 DELIVERY SYSTEMS FOR RNA-INTERFERENCE

### 18.3.1 Viral Delivery Systems

In theory, RNAi can be triggered in many different ways. Most of the proposed clinical applications incorporate the double-stranded RNA molecules (siRNAs) that are typically 19 to 23 nucleotides in length and consequently have a molecular weight of 13 to 15 κDa and 38 to 46 negative charges [24]. As a result, they do not easily penetrate hydrophobic cellular membranes without assisting carriers. In addition unprotected siRNAs are generally rapidly degraded by serum nucleases. However, the intracellular entry and translocation into cytoplasm (or nucleus), where the RNAi machinery is located, is a prerequisite for gene silencing activity. This brings the necessity of the delivery vehicle, which ideally should facilitate intracellular entry into target cells and facilitate endosomal or lysosomal escape into the cytoplasm. Although it has its own hurdles, combining RNAi with viral gene therapy vectors appears to be a powerful approach when a persistent suppression of target is mandatory [24]. Viral approaches facilitate effective siRNA delivery into many difficult-to-transfect cell types, including primary cells. Designing viral RNAi vectors became feasible only after the discovery of RNAi machinery through promoter driven expression of short hairpin RNAs (shRNAs) [25]. This strategy involves cloning an oligonucleotide containing the siRNA sequence into plasmid or viral vectors to endogenously express shRNA. This should be further processed in the cytoplasm to siRNA. Because these shRNA expression cassettes are extremely small, they have the advantage of being packaged into even the smallest known viral vectors.

The use of retroviral vectors was among the first vectors used as transfer vehicles for hairpin RNA–expressing plasmids [26]. This approach involves the expression of a shRNA transcript that is processed endogenously to a siRNA. These retroviruses, by integrating their genome stably into the host cell DNA, effectively induce gene silencing and allow long-term, stable reduction of gene expression, which is critical for understanding and studying how reducing expression of disease-relevant genes cause disease phenotypes over extended period of time [24]. Because the retroviral entry and genome integration do not require viral protein synthesis, all of the viral genes in the genome can be replaced with foreign sequences. Because these viruses are likely to produce therapeutic siRNA, the viral envelope seems like a main factor capable of defining cellular tropism for this type of delivery. Tropism of these

particles can be modified through incorporation of alternative viral envelopes. Also, to maximize the safety and efficacy, retroviral RNAi vectors can be targeted to the cell types requiring therapeutic intervention.

Adenoviruses are frequently used for experimental gene therapy and had been popular for gene therapy trials because of their attractive features, including infection of both dividing and nondividing cells, high levels of transgene expression, and the ability to grow in high titers [27]. These viruses replicate in the nucleus of the mammalian cells but do not integrate into the host genome. In addition, these adenoviruses can package about 8 to 10 kb of foreign DNA. These viruses very efficiently enter the cells by a receptor-mediated pathway. The viral fiber protein binds to the cell surface receptors such as CAR (in case of group A adenovirus serotype) or CD46 (or group B serotype) followed by a secondary interaction in which the penton base protein interacts with an integrin and results in entry into the host cells [28]. These adenoviral vectors are generally a common delivery method to introduce shRNA-expression cassettes into target cells. Several groups have reported the use of adenoviral vectors for transduction of RNAi-based therapy using a hairpin-encoding adenoviral system.

Adeno-associated viral (AAV) vectors are another class of promising vectors for siRNA delivery based on several advantages over existing viral vectors. They have also been tested in clinical studies in multiple tissues [29]. They are not known to be pathogenic and have a broad range of possible target cells, including nondividing cells. Their small single-stranded DNA genomes contain only two genes, and these can be easily replaced with foreign ones, which leave the terminal inverted terminal repeats (ITRs) to allow high-level expression of the insert. Given the packaging limit of 5 kb, AAV accommodates at least eight individual shRNA expression cassettes [30,31]. Pseudotyping of AAV allows delivery of shRNA cassette to specific cells or tissues. In addition, AAV vectors show low reactivity with cellular immune responses. These are also nonintegrating and therefore pose only minimum risks of insertional mutagenesis.

Although viral vector systems seem to be a major delivery system for shRNA, a number of limitations are associated with each of them. One of the major disadvantages of adenoviral vectors is a problem of repeated administration, which triggers a strong immune response, potentially limiting the effectiveness [24]. Additionally, the accumulation of adenoviral vectors in the liver leads to severe liver toxicity. Retroviral vectors, on the other hand, also suffer from limitations such as an inability to infect nondividing cells, silencing or position effects on gene expression, and low titers. Adenoviral and AAV vectors are nonintegrating and therefore pose a minimal risk of insertional mutagenesis. But the genetic information seems to be less stably conserved and may be lost during repetitive cell division [24]. Although these vectors efficiently transduce dividing and nondividing cells, they may be inadequate for long-term gene replacement therapy.

### 18.3.2 Nonviral Delivery Systems

Although the viral vectors are very efficient delivery vehicles and have distinct advantages over plasmid DNA delivery, they can be toxic and immunogenic, can

potentially activate oncogenes, or can deactivate tumor suppressor genes. Because of these issues, the nonviral synthetic nanoparticle system has become an increasingly popular alternative for siRNA and miRNA delivery. Therefore, synthetic lipids and polymers have been developed to offer alternatives to viral vectors for nucleic acid delivery applications. These nonviral nanoparticle systems are designed and formulated very carefully to have appropriate dimensions for cell entry and endocytosis. They are also built to avoid stimulation of the immune system. Clearance of larger molecular mass lipids or polymers requires them to be biodegradable. The use of biodegradable materials would have linkages that can be cleaved inside the cell to reduce toxicity. Some of the commonly used such delivery systems include lipid-based carriers, polymer systems, peptides and proteins, and conjugates [32,33]. The most commonly and widely used lipid systems are liposomes, which been used for delivery of nucleic acids for more than 20 years. Liposomes form unilammellar or multilammelar structures. They are globular vesicle in nature with an aqueous core and phospholipid bilayer [32,33]. Because of this amphipathic nature, they efficiently incorporate wide variety of hydrophilic and hydrophobic drugs. Liposomes are created using natural body constituents such as lipids, sterols, and so on and are biocompatible and biodegradable. Cationic lipids are the most commonly used components of lipid-based siRNA delivery systems, and they consists of three major parts—a cationic head group, a lipophilic tail group, and a connecting linker. The structure of the head group, the carbon chain length of the tail group, and the nature of the linker mainly contribute to the transfection efficiency and the toxicity of the siRNA carriers. Transfection efficiency and endosome escape are known to be enhanced with a smaller hydrophilic head group and bulky alkyl side chains [33]. These lipid-based carriers are being used successfully to deliver siRNA to targets such as liver, endothelium, and solid tumors. Although these cationic liposomes are the most popular siRNA delivery agents so far, there are some concerns still remain regarding their safety for therapeutic use because certain cationic lipids have been reported to show severe cytotoxicity *in vitro* and *in vivo* [34]. Neutral leptosomes are another class of liposomes that have already shown good safety and efficacy records in humans. Once such example that received Food and Drug Administration (FDA) approval for human use is Doxil [32]. The poly(ethylene) glycol (PEG)–modified long-circulating liposomes are clinically approved delivery system for doxorubicin and therefore represent a viable option for delivering siRNA in humans [35]. Although this has been currently used for treatment of number of different cancer indications, its further development was limited after cationic liposome development. Although cationic liposomes have been used to efficiently deliver siRNA *in vitro* and *in vivo*, with the realization that significant toxicities associated with cationic charged molecules, neutral liposomes have reemerged as promising carriers for siRNA. However, the initial incorporation of siRNA and stability seem to still be problematic in these neutral systems, and these limitations are currently being addressed by researchers using novel strategies. In addition, it has been reported that with repeat dosing regimens of PEG-modified liposomes, the antibodies specific for PEG-modified particles have been generated, which will end up compromising the efficacy in the long run [36,37].

Conjugating small molecules, peptides, proteins, polymers, and aptamers to siRNA comprise another class of carriers and are known to improve the stability, cellular internalization, or cell-specific active targeting delivery [32,35,38]. Cholesterol-conjugated siRNA, upon systemic administration, silenced the expression of an endogenous gene encoding apolipoprotein (apo) B in the liver and jejunum and reduced the plasma apo B levels as well as the total cholesterol level, but the naked siRNA did not show any activity in these tissues [39]. However, it has been demonstrated that these conjugates need to be administered at very high doses to be active in mice. Surprisingly, no off-target effect or immune stimulation was reported despite of the higher doses used. However, an extensive cell surface binding of lipophilic oligonucleotide conjugates has been reported to interfere nonspecifically with normal cellular processes. This actually necessitates a detailed safety evaluation of this approach. Endosomolytic agent (amphipathic poly[vinyl] ether)–modified siRNA, upon systemic administration, effectively reduced the expression levels of two endogenous genes in mouse liver [40]. The endosomolytic agent is known to enhance the endosomal escape after endocytosis. Conjugating antibody is another way of increasing the specificity of siRNA delivery and minimize the off-target effects. One such example was the delivery of F105-P–siRNA conjugate to HIV-infected cells [41]. This did not trigger the interferon responses but reduced the HIV replication in a difficult-to-transfect HIV infected CD4 T cells. One more way of increasing the cell-specific delivery is by linking siRNA to an RNA aptamer or aptamer–siRNA chimeras. Upon intravenous injections, PEG-modified aptamer chimeras resulted in a significant regression of prostate-specific membrane antigen (PSMA)–expressing tumors [42]. Although the studies suggested the potential use of aptamers for targeted delivery of siRNA drugs, nuclease susceptibility of aptamer ligands may limit their application in systemic treatments, and the possibility of premature degradation of siRNA in the endosomal compartment because of the lack of endosomal escape machinery may require additional functionality.

Cationic polymers also readily bind and condense large nucleic acids and serve as efficient transfection agents. Because of this cationic nature, they were also shown to stimulate endocytosis and endosome escape. These polymers are widely divided into two classes, natural polymers (chitosan, atelocollagen, and cyclodextrin) and synthetic polymers such as polyethylenimine (PEI), poly-L-lysine (PLL), and dendrimers [33].

Cyclodextrin, a natural polymer, has been developed as a delivery vehicle to efficiently deliver siRNA to tumors [43]. β-Cyclodextrin–containing polycations have been self-assembled with adamentane–PEG5000 and transferrin ligand to target transferrin receptors on the cell surface. These nanoparticles seemed to be stable in the bloodstream. Unlike the cationic liposomes, transferrin targeted cyclodextrin polymer particles did not illicit any immunostimulatory effects in mouse models. They also demonstrated good safety profile in nonhuman primates [44]. Not only did they demonstrate good efficacy in number of different preclinical models, but they also showed activity and efficient gene silencing in human cancer patients in clinic [45]. PEI is a synthetic polymer, and it has been broadly investigated for nucleic acid delivery. PEG-modified PEI with arginine–glycine–aspartic acid (RGD) ligand has been extensively studied by Temming et al. [46], for siRNA delivery to target

angiogenesis [46]. Because the commonly used branched PEI is generally known to cause severe toxicity, the use of higher molecular weight unmodified PEI is likely to be limited. Several groups have been successful in minimizing the toxicity by using low-molecular-weight or biodegradable PEI, although this favors the plasmid delivery rather than the siRNA delivery in mouse models. Another approach was also initiated to synthesize a ketalized PEI carrier. Branches of PEI were modified with acid-degradable amine groups through ketal linkages [47]. These bonds rapidly break at a low pH to release the siRNA. Hybrid of these approaches suggests the possibility of a nontoxic PEI carrier to deliver siRNA. As an alternative to PEI carriers, poly(lactic-*co*-glycolic acid) (PLGA) is another extensively studied copolymer for delivery. Compared with cationic polymers and lipids, it has the advantage of lower toxicity. Tertiary amine modified polyvinyl alcohol backbones grafted to PLGA yielded rapid degradation properties for siRNA release. Incorporation of PEI into PLGA nanoparticle further improved the loading and activity. Dendrimers are another class of synthetic, cationic macromolecules that are being used as a carrier for small molecular drugs and large biomolecules [33]. Although the most advanced delivery system at present includes a cationic group for ionic interaction with siRNA (PEG for steric hindrance, an endosomolytic group for endosome escape, and a targeting ligand for specific delivery), several researchers have been working to come up with a noncondensing lipid polymer agent as an siRNA or miRNA carrier to minimize the toxicity effects coming from the cationic charged molecules.

## 18.4 MULTIFUNCTIONAL NANOSYSTEMS FOR DELIVERY OF RNA-INTERFERENCE THERAPEUTICS

### 18.4.1 Nanoparticle-Based Targeted Delivery

Encapsulation of oligonucleotides and siRNAs in nanoparticles can offer several major advantages over conventional modes of delivery in the management of diseases such as cancer [48,49]. For instance, apart from protecting the payload from degradation in the bloodstream, nanoparticles and liposomal delivery systems can ferry the drugs and oligonucleotides selectively to solid tumor tissues based on a phenomenon called the EPR effect discovered by Matsumura and Maeda three decades ago [50].

Tumor cells divide and multiply at phenomenal rates and posses devastating invasive potentials. When the tumor lesion reaches approximately 1 to 2 mm in diameter, the tumor starts to form "neovasculatures" by a process called angiogenesis or development of new blood vessels, which starts to cater to the nutritional and oxygen demands of the growing tumor [51]. The tumor blood vessels are also found to be aberrant and "leaky." Furthermore, tumor tissues often lack a lymphatic drainage system [50,52,53]. The tumor microenvironment is thus highly disorganized in architecture [54]. Also, most solid tumors have excessive production of vascular permeability mediators such as vascular endothelial growth factor (VEGF),

bradykinin, prostaglandins, matrix metalloproteinases (MMPs), nitric oxide, and peroxynitrite [55–58]. The elevated levels of the vascular permeability mediators coupled with the anatomical and pathophysiological abnormalities of the tumor vasculature leads to extensive extravasation of blood plasma components, macromolecules, and nanoparticles into the tumor interstitium [59]. It is thus possible to achieve "passive tumor targeting" and a very high local concentration of the nanoparticles in the tumor tissues. In general, drugs and genes encapsulated in macromolecular delivery systems such as polymer conjugates, liposomes, polymeric nanoparticles, and micelles are thus able to exploit this unique phenomenon to accumulate selectively in solid tumor tissues [60–64].

The EPR effect has been found to be more pronounced if the nanoparticulate delivery systems are designed to evade the mononuclear phagocytic system (MPS), thus prolonging their circulation half-life in the blood. In this regard, grafting of amphiphilic polymers such as PEGs to the nanoparticles has been found to be very effective in providing stealth characteristics that enable MPS escape, thereby rendering a long plasma circulation time [65] (Fig. 18.3).

As described earlier, passive targeting itself can be a highly effective mechanism for delivering nanoparticles loaded with oligonucleotides and siRNAs for moderate and highly vascularized solid tumors; however, their delivery to avascular, hypovascular, or necrotic regions of tumors still remains a great challenge [66]. Also, passive targeting using the EPR effect does not apply for diseases other than solid tumors and some cases of inflammatory disorders. In this regard, "active ligand-based targeting" using antibodies or peptides that can selectively bind to receptors or antigens overexpressed on the surface of diseased cells and tumors can be more promising [67] (see Fig. 18.3). Furthermore, the delivery efficiency and target specificity of passively targeted nanosystems can be improved significantly when tumor targeting agents are also made part of the nanodelivery systems [68]. In our group, we have developed one such nanosystem that utilizes epidermal growth factor receptor (EGFR) peptide conjugated nanoparticles for active targeting to multidrug-resistant ovarian cancer cells that overexpress EGFR [69,70]. In another example of active targeting, RGD tripeptide was coupled to nanoparticles to target $\alpha_5\beta_5$ or $\alpha_5\beta_3$ integrin receptors that are overexpressed on vascular endothelial cells of angiogenic blood vessels of proliferating tumors [71]. Werner et al. [72]. have used folate-based active targeting to deliver nanoparticles to ovarian cancer that overexpress folate receptors. Such particles are internalized by active transport via receptor-mediated endocytosis [73]. Nucleic acid constructs such as aptamers that can selectively bind to PSMA on prostate cancer cells are also being explored as active targeting ligands for diseases such as prostate cancers [74].

Active targeting using antibodies [75] and peptides coupled to nanoparticles thus in effect provides a more selective secondary targeting via binding or intracellular trafficking of the siRNA–drug payload to the target cells [67,76] after the primary (passive) targeting based on the EPR effect (see Fig. 18.3). Such multifunctional smart delivery systems are currently intensely pursued and have the potential to revolutionize nanoparticle-based RNAi therapeutics development [77].

### 18.4.2 Advantages of Multifunctionality

The aim of developing a multifunctional nanoparticulate delivery system is to achieve several goals using a single "nanoconstruct." For instance, a nanoparticle delivery system can be designed with a low, moderate, or high level of complexity depending on the requirements of the target disease or function in the body such as:

1. Protection of the payload (e.g., siRNA) from degradation on systemic delivery and elimination of off-target effects associated with therapeutic agents [78]
2. Enabling long circulation half-life *in vivo* by surface functionalization of nanoparticles with amphiphilic molecules such as PEG that can help evade the immune system and reduce clearance by the MPS [79,80]
3. Taking advantage of passive tumor targeting strategies based on the EPR effect [81]
4. Loading or encapsulating the nanoparticles with single (and often large doses of) therapeutic agent or co-deliver multiple agents such as siRNA and drugs that works synergistically to have a compounded effect [82,83]. In this regard, polymeric nanoparticle–based delivery also offers the flexibility to devise the system to have spatial and temporal control or controlled erosion characteristics based on the nature and choice of the biodegradable polymer used for constructing the nanosystems [84–86]. For example, the delivery vehicle can be engineered to release one drug or oligonucleotide concomitantly with another agent or, if desired, after a time lapse or in a controlled fashion based on the requirement of the disease target [84]. In this regard, in our laboratory, we are developing a combinatorial-designed library of novel biodegradable and biocompatible polymers that can self-assemble in the presence of oligonucleotides and drugs to form stable nanoparticles as shown in Figure 18.4 [87,88]. The advantage of such systems is the diverse choice of polymers with varying functionality that could be screened simultaneously based on a "mix and match" type screening to arrive at the right choice of materials that can be tailored for specific disease targeting [87,88].
5. The nanoparticles could also be surface decorated with targeting ligands such as antibodies or peptides that can help locate, bind, or internalize the nanoparticles into the diseased cells or can be incorporated with agents that can trigger the release of the payload (drugs or genes) in specific location or facilitate the drug escape from organelles (e.g., lysosomes) within the cells [63,89–92].
6. Targeted and nontargeted nanoparticles can also be designed to aid intracellular distribution of the payload that can be critical for many drugs and genes whose sites of action are generally located in the cytoplasm or the nucleus [93]. For example, plasmid DNA, oligonucleotides, miRNA, siRNA, peptides, and proteins have their targets located in the cytoplasm or nucleus. Thus, there is a need for these molecules to be transported inside the cell [93,94]. More importantly, intracellular trafficking of drugs and genes is more challenging for refractory diseases such as cancers that are equipped with

**FIGURE 18.4** Multifunctional nanosytems for targeted therapeutics. Schematic representation of a multifunctional targeted immunoliposome (a) and a multifunctional self-assembled targeted nanoparticle (b) that can be formulated from their corresponding building blocks. The multifunctional nanosystems can be engineered by self-assembly of polymers or lipids containing various functionalities such as amphiphilic block copolymers to facilitate formation of stable nanoparticles loaded with drugs, genes, and imaging agents; antibody and peptides for targeting; and surface functionalized with amphiphilic poly(ethylene) glycol (PEG) chains for enabling long circulation half-life *in vivo*. siRNA: small interfering RNA.

active drug efflux pumps such as P-glycoprotein and multidrug-resistant proteins that are responsible for developing multidrug resistance (MDR) [95]. In such cases, nanoparticle-based delivery systems have shown to evade the drug efflux pathway, thus increasing the intracellular delivery efficiency of drugs and genes [96,97].

7. Nanoparticles can be tagged with imaging agents such as optical dyes, radiotracers, and contrast agents for simultaneous disease detection or visualization and treatment [98,99]. Such multifunctional delivery systems (see Fig. 18.4), have the advantage of performing multiple tasks such as visualizing the sites of localization of nanoparticles, monitoring the *in vivo* fate, efficiently delivering the payload and measuring dose response in patients [100]. Such functions can thus be performed noninvasively and recorded simultaneously in real time using a single nanoconstruct.

## 18.5 ILLUSTRATIVE EXAMPLES OF NANOPARTICLE-MEDIATED SMALL INTERFERING RNA DELIVERY

### 18.5.1 Small Interfering RNA Delivery in Cancer

As discussed in prior sections, gene therapy based on the RNAi mechanism has been well established and has currently become a major area of research that holds great promise for the management of diseases such as cancers. Although siRNAs have high efficiency and specificity, the major hurdles that still remain are its delivery to target tumor cells and intracellular trafficking after localization in the sites of interest [101].

Researchers from Park's group have developed a polyelectrolyte complex micelle-based VEGF siRNA delivery system for antiangiogenic gene therapy [102]. The complexation of the PEG-conjugated VEGF siRNA was achieved by charge interaction with PEI. This complex formed a stable core-shell nanostructure with the PEI/siRNA forming the central core and PEG chains forming the corona. Intravenous (IV) and intratumoral injection of the micelles in mice demonstrated significant inhibition of VEGF expression in the tumor tissue and suppressed tumor growth without detectable toxicities [102]. Furthermore, to confirm the feasibility of siRNA-based gene therapy and imaging *in vivo*, optical imaging was undertaken using a Cy5.5-labeled siRNA. The Cy5.5-labeled siRNA containing polyelectrolyte complex micelles predominantly accumulated in the tumor, affirming the feasibility of this approach [102].

To overcome the dose-limiting side effects of conventional chemotherapeutic agents and the therapeutic failure caused by MDR, we designed and evaluated a novel biocompatible lipid-modified dextran-based self-assembled polymeric nanosystem that could encapsulate MDR-1 siRNA as well as anticancer drugs such as doxorubicin [49,103]. Furthermore, to image the transfection efficacy of siRNA-loaded nanoparticles on cell lines, we used an EGFP (green fluorescence protein) expressing BHK-21 cells and performed confocal fluorescence microscopy to visualize the downregulation of EGFP. It was observed that the EGFP siRNA was efficiently incorporated into cells and effectively inhibited the expression of EGFP in a dose-dependent manner. Similarly, the MDR1 siRNA-loaded dextran nanoparticles efficiently suppressed P-gp expression in the drug-resistant osteosarcoma cell lines. A combination therapy of the MDR1 siRNA-loaded nanocarriers with doxorubicin revealed pronounced increase in doxorubicin uptake in the nucleus (assessed by confocal fluorescence microscopy imaging) of multidrug-resistant cells. These results demonstrate that our approach may be useful for reversing drug resistance by increasing the amount of drug accumulation in MDR cells. Thus, delivery using nontoxic and biocompatible dextran-based nanosystems offers a versatile platform for incorporation of multiple payloads for simultaneous imaging and delivery of therapeutic molecules that can be translatable for human clinical applications.

In another study, Huh et al. [104] designed a siRNA delivery system containing glycol chitosan biodegradable and biocompatible polymer (GC) and PEI. The

polymers were conjugated with 5β-cholanic acid (CA) to stabilize the nanoparticles and endow them with tumor-homing ability. The nanoparticles were formed by mixing GC-CA and PEI-CA to form self-assembled nanostructures (GC–PEI nanoparticles) caused by the strong hydrophobic interactions of 5β-cholanic acids in the polymers. The cationic charge on the GC–PEI nanoparticles was used to complex with the negatively charged red fluorescence protein (RFP) gene silencing siRNA designed to inhibit RFP expression. *In vitro* studies with RFP expressing B16F10 tumor cell incubated with siRNA–GC–PEI nanoparticles revealed time-dependent cellular uptake of the nanoparticles and led to specific mRNA knock down. More importantly, the siRNA-loaded nanoparticles displayed significant inhibition of RFP gene expression in RFP/B16F10-bearing mice models, demonstrating their potential as a promising vector for siRNA delivery [104].

Medarova et al. have developed a dual-purpose probe for *in vivo* delivery and simultaneous imaging of siRNA accumulation in tumors by using high-resolution magnetic resonance imaging (MRI) and near-infrared (NIR) *in vivo* optical imaging techniques [105]. The siRNA was covalently conjugated to nanoparticles consisting of NIR dye conjugated magnetic nanoparticles. Furthermore, the nanoparticles were decorated with specific membrane translocation peptide that enables their intracellular delivery and cytosolic availability [105]. Taken together, the study demonstrates the feasibility of tracking the tumor uptake and silencing ability of the siRNA conjugated nanoparticles *in vivo* [105].

In another study, Kumar et al. [106] used superparamagnetic iron oxide nanoparticles as a construct for delivery of siRNA to solid tumors and for combined optical and MR imaging. The nanoconstruct, apart from performing its function as a vehicle for siRNA delivery, also served as a tool to study basic tumor biology and therapy [106]. The nanoconstruct consisted of magnetic nanoparticles (for MRI), a Cy3 fluoropore (for optical imaging), a targeting peptide (EPPT) that could home to a specific antigen (uMUC-1) overexpressed by majority of human breast cancer cells, and a synthetic siRNA that downregulates the *BIRC5* antiapoptotic gene in breast cancer cells [106]. The nanoconstruct demonstrated specific tumor uptake and significant downregulation of the *BIRC5* gene in animal tumor models. More importantly, the tumor uptake could be visualized both by MRI and NIR optical imaging [106].

### 18.5.2 Small Interfering RNA Delivery in Inflammatory Diseases

Nanoparticle- and microparticle-based oral gene silencing using siRNA-encapsulated polymeric systems has been very promising for inflammatory disorders. In a recent study in our group, we evaluated the downregulation of tumor necrosis factor α (TNF-α) by oral RNAi therapy. Control (scrambled sequence) or TNF-α–specific siRNA were encapsulated in type B gelatin nanoparticles and further entrapped in poly (epsilon-caprolactone) (PCL) microspheres to form a nanoparticles-in-microsphere oral system (NiMOS). It was observed that successful gene silencing led to decreased colonic levels of TNF-α, suppressed expression of other proinflammatory cytokines (e.g., interleukin [IL]-1β, interferon [IFN]-γ) and chemokines (MCP-1), an increase in body weight, and reduced tissue myeloperoxidase activity in murine models. Results

of this study established the clinical potential of a NiMOS-based oral TNF-α gene silencing system for the treatment of inflammatory bowel disease as demonstrated in an acute colitis model [107].

A cell cycle regulatory molecule, cyclin D1 (CyD1), is a well-known therapeutic target for cancer. It is also strongly overexpressed at the sites of inflammation. To study the role of cyclin CyD1 in inflammation, Peer et al. [108] devised a strategy to selectively silence CyD1 in leukocytes *in vivo*. A targeted nanoparticle system (tsNPs) was loaded with CyD1–siRNA. Then a specific antibody to β-7 integrin (β-7 I) was used to target specific subset of leukocyte involved in gut inflammation. It was observed that the systemic administration of β-7 I–tsNPs silenced the CyD1 in leukocytes and reversed experimentally induced colitis in animal models by suppressing the leukocyte production and T-helper cell 1 cytokine expression. The study revealed that CyD1 could be an antiinflammatory target, and the use of similar targeted nanoparticle-loaded siRNAs could be explored for other therapeutic settings [108].

siRNAs have also shown major implications for the management of diseases such intestinal inflammation. Wilson et al. has shown TNF-α silencing using siRNAs loaded in thioketal nanoparticles (TKNs) for targeted inhibition of gene expression in the intestines of murine models with ulcerative colitis [109]. In this case, protection of the siRNA during delivery and its targeting to the intestinal tissues was found to be critical because the systemic depletion of cytokines could cause adverse side effects. Although various delivery vehicles have been developed to orally deliver therapeutics to intestinal tissue, none of these strategies has demonstrated the ability to protect siRNAs from the harsh environment of the gastrointestinal tract and target its delivery to inflamed intestinal tissue. In this regard, the delivery vehicle developed by Wilson et al. [109], termed TKNs, could direct orally delivered siRNA to sites of intestinal inflammation and thus inhibit gene expression in inflamed intestinal tissue. TKNs were made from a polymer, poly-(1,4-phenyleneacetone dimethylene thioketal), that could degrade selectively in response to reactive oxygen species (ROS). Therefore, when delivered orally, TKNs could trigger the release of siRNA in response to the abnormally high levels of ROS specific to sites of intestinal inflammation. The study thus provides concrete evidence that orally administered TKNs loaded with siRNA against the proinflammatory cytokine TNF-α could diminish TNF-α messenger RNA levels in the colon and protect mice from ulcerative colitis [109].

To maintain the integrity of blood–brain barrier (BBB), Bonoiu et al. [110] have evaluated MMP-9 gene silencing using a quantum dot (QD)–siRNA nanoplex delivery. MMPs, particularly MMP-9, are found to be involved in the neuroinflammation processes leading to disruption of the BBB, worsening the condition of neurologic diseases such as HIV-1 AIDS, dementia, and cerebral ischemia. In this regard, nonviral vectors such as nanoparticles have been proposed to have great potentials for their treatment. Bonoiu et al. [110] found that QDs complexed with MMP-9-siRNAs formed a stable nanoplex that could be used for studying the specificity and delivery efficiency for downregulating the expression of MMP-9 gene in brain microvascular endothelial cells (BMVEC), which constituted the BBB. It is hypothesized that silencing MMP-9 gene expression in BMVECs and leukocytes

may help prevent breakdown of the BBB and in turn inhibit the subsequent invasion of central nervous system (CNS) by infected and inflammatory cells. Indeed, it was observed that silencing of MMP-9 gene expression resulted in decrease in endothelial permeability and upregulation of ECM proteins such as collagen I, IV, and V as a result of reduction of transendothelial resistance across the BBB in the *in vit*ro BBB model [110]. MMP-9 gene silencing also resulted in an increased expression of the gene tissue inhibitor of metalloproteinase-1 (TIMP-1). These results corroborate the existence of a delicate balance between the MMP-9 levels and its natural inhibitor TIMP-1 and its role in maintaining the basement membrane integrity. The study by Bonoiu et al. [110] reinforces the role of novel nanoparticle-based siRNA delivery systems in modulating the MMP-9 activity in MMP-9–producing cells that may prevent neuroinflammation and preserve the integrity of the BBB [110].

### 18.5.3 Small Interfering RNA Delivery in Other Diseases

The RNAi mechanism offers the potential for new and effective therapies for a wide variety of diseases other than cancers, such as rheumatoid arthritis. It is well known that TNF-α plays a key role in the progression of rheumatoid arthritis and is an important target for antirheumatic therapies [111]. TNF-α expression can be silenced with siRNA, but its efficacy depends on efficient and safe siRNA delivery vectors. Jensen et al. [112] aimed to identify polymeric nanocarriers for anti–TNF-α siRNA with optimal efficacy and minimal side effects *in vitro*. It was observed that dextran nanogels and polyamidoamine (PAMAM) dendrimers of generations 4 and 7 mediated concentration-dependent gene silencing with minor toxicity [112]. These systems are thus expected to be suitable for systemic delivery of siRNA.

Although the clinical development of new RNAi-based technology for treating diseases such as pulmonary disorders is still limited, there is a wide scope for polymeric and liposomal delivery systems for treatment of such diseases. Sparks et al. [113] have recently reported the development of a structurally versatile class of cationic lipopolyamines designed particularly for siRNA delivery, which showed high levels of target transcript knockdown in a range of cell types *in vitro*. A primary benefit of their lipid system was the ease with which they could be covalently modified with functional molecules. On systemic administration in animal models, the nanoparticles prepared from stearylamine lipid modified with methoxy-polyethyleneglycol (m-PEG) containing a siRNA targeting the caveolin-1 (Cav-1) transcript caused up to 60% reduction of the Cav-1 transcript, specifically in lung tissue after 48 hours compared with treatment with nonsilencing siRNA [113]. Moreover, the modification of the nanoparticles with mPEG showed reduced toxicity associated with IV administration, demonstrating the potential use of using lipid-based RNAi nanotherapeutics for treating pulmonary disease [113].

In 2009, Woodrow et al. [114] were the first to report the use of biodegradable polymeric nanoparticles as safe and effective delivery vehicles for siRNA-induced gene silencing in the genital tract. Although siRNA delivery using conventional liposome-based systems have been useful for protection against infectious disease and gene silencing in the genital tract, commercially available lipids are found to be

toxic to the epithelial mucosa. In their alternative approach, Woodrow et al. [114] used nanoparticles derived entirely from FDA-approved materials. A bolus high dose of siRNA-loaded nanoparticles administered topically to the mouse female reproductive tract resulted in efficient and prolonged gene silencing [114]. It was observed that the knockdown of gene expression was seen not only in the vaginal lumen but also in the uterine horns that are located at distal sites from the topically administered area. In addition, the nanoparticles could penetrate deep into the epithelial tissue, demonstrating their pronounced gene silencing effect [114].

Zhang et al. [115] have reported that siRNA targeting the NS1 gene delivered using nanoparticles may provide an effective inhibition of respiratory syncytial virus (RSV) infection in humans. The role of NS1 gene in modulating RSV infection was studied using a plasmid-borne siRNA targeting the NS1 gene (siNS1) [115]. It was observed that RSV replication was reduced in A549 cells, but not interferon-deficient Vero cells, transfected with siNS1. siNS1-induced upregulated expression of interferon and interferon-inducible genes in A549 cells. It was also reported that there was overproduction of type 1 interferon and induced differentiation of naive $CD4^+$ T cells to T-helper type 1 (TH1) cells in siNS1-transfected human dendritic cells upon RSV infection [115]. Intranasal administration of siNS1 nanoparticles before or after RSV infection showed remarkably decreased virus titers in the lung and decreased inflammation and airway reactivity compared with controls in mice models [115]. This study demonstrated that inhibition of RSV infection using siRNA nanoparticles targeting the viral NS1 gene could be achieved *in vivo* [115].

It is well known that HIV infection of the CNS is the principle cause of HIV-associated dementia in adults and encephalopathy in children. In this regard, therapies using siRNA encapsulated in nanoparticles may facilitate transport across the BBB. Researchers from the Muñoz–Fernández group have used the 2G-NN16 amino-terminated carbosilane dendrimer as a method for delivering siRNA to HIV-infected human astrocytes [116]. It was reported that a gradual time-controlled degradation of the 2G-NN16 dendrimer resulted in the liberation of its siRNA cargo between 12 and 24 h [116]. Furthermore, the siRNA/2G-NN16 dendriplexes were able to transfect human astrocytes successfully even after crossing the BBB in an *in vitro* model. More importantly, the transfected siRNA was observed to exert a biologic effect because the dendriplexes exhibited downregulation of the housekeeping gene GAPDH and reduced the replication of HIV-1 strains X4-HIV NL4-3 and R5-HIV BaL in human astrocytes [116]. These results demonstrate that dendrimers could be successfully used for siRNA gene silencing without causing apparent toxicities.

Huang and King [117] have developed an immobilized siRNA nanoparticle-based platform technology for efficient gene silencing in targeted cells in the circulation especially for diseases derived from disorders of blood cells. To create targeted liposome-loaded siRNA delivery systems, P-selectin was covalently attached to the surface of PEG-modified liposomes. The targeted liposomes were found to effectively absorb onto the inner surface of micro-renathane tubing. The liposome-coated surfaces could not only capture target cells from physiological shear flow and efficiently deliver the encapsulated siRNA into adherent cells but also

exhibit pronounced silencing of the targeted gene neutrophil elastase [117]. The device developed by Huang and King could further create a high and localized concentration for siRNA delivery in the circulatory system, providing circulating target cells (e.g., stem cells) adequate time to interact with therapeutic materials [117].

## 18.6 ILLUSTRATIVE EXAMPLES OF NANOPARTICLE-MEDIATED MICRO RNA DELIVERY

### 18.6.1 miRNA and Antagomir Delivery in Cancer

When oncogenic miRNAs are upregulated, they block the tumor suppressor genes and lead to tumor formation. On the other hand, when there is downregulation or loss of miRNAs with suppressor functions, they may increase the translation of oncogenes and hence formation of tumors [118–120]. One of the strategies to target overexpressed miRNA expression in cancer is the use of oligonucleotides or antagomirs to block the expression. Antagomirs are a novel class of chemically modified stable oligonucleotides consisting of 20 to 24 bases that are used to block the functions of endogenous miRNAs. The other one involves the use of miRNA mimics to substitute for the loss of expression of a tumor suppressor miRNA. The key challenge in achieving effective miRNA therapeutics in those cases is the development of an efficient delivery system that can specifically deliver antagomirs or miRNA mimics to target cells in living animals. To overcome these delivery hurdles, nonviral and viral strategies have been explored. The nonviral strategies include encapsulation of chemically modified oligonucleotides in liposomes or polymers [118]. Liposomes are composed of a phospholipid bilayer with an enclosed aqueous compartment. During complexation, they interact with oligonucleotides to form complexes that are stabilized by electrostatic interactions. These liposomes protect the oligonucleotides from degradation by nucleases and increase the circulation half-life.

Let-7 was one of the best studied miRNAs and was found to be altered in the majority of human lung cancers [121,122]. Bader and his group [121] identified this tumor suppressor miRNA in majority of non–small cell lung cancer (NSCLC) cells and patient samples and used the concept to reintroduce this miRNA mimics to cells and tumors to reactivate cellular pathways to drive a therapeutic response. Studies have shown that the reduced let-7 was significantly associated with shortened postoperative survival times and that overexpression resulted in the inhibition of lung cancer cell growth [123]. Using a neutral lipid delivery system, Bader et al. efficiently delivered the miRNA mimic to cells and demonstrated significant growth inhibition and proliferation [123]. They also demonstrated lung tumor growth inhibition in NSCLC tumors (H460) that lack the expression of let-7 using the same delivery system [123]. In addition, it was demonstrated that let-7 works against the oncogene K-ras that has crucial role in proliferation of lung cancer cells, especially in the cells with K-ras mutations. Given this information, this group

also demonstrated significant tumor growth inhibition and antitumor efficacy in a genetically engineered K-ras mutated oncogenic mouse model, a model that very closely resembles actual human lung cancer [124].

EGFR overexpression is often found in majority of the NSCLC samples. Although the EGFR-tyrosine kinase inhibitor has a striking effect in NSCLC with longer survival rates, the efficacy is attributed to the development of EGFR-TKI–acquired resistance because of additional mutations. Thus, a method to suppress the restored EGFR pathway is needed to overcome the resistance. Rai et al. have developed an approach to deliver miRNA (miRNA7) that targets multiple sites in the 3′ UTR of EGFR mRNA to suppress the EGFR expression [125]. Compared with the conventional targeting therapies such as antibodies and inhibitors, the miRNA strategy seems to be independent of unexpected conformational changes caused by secondary mutations. They used a cationic liposome system to deliver miRNA7 expressing plasmid and demonstrated significant inhibition of cell growth in number of different lung cancer cells. Delivery of miRNA7 also resulted marked tumor regression and EGFR suppression in mouse xenograft lung models, which ultimately overcomes the EGFR-tyrosine kinase inhibitor resistance in lung cancer cells and tumors [125]. Another group has developed a transferrin targeted, protamine containing liposomes, to deliver miRNA. miR29b is a member of miR29 family, which downregulates the cellular expression of antiapoptotic Mcl-1 proteins. The formulation was designated as Tf-LPmR, has protamine to increase the delivery efficiency and transferrin ligand for receptor-mediated internalization in leukemia cells (K562) that overexpress transferrin receptors. It was demonstrated that this Tfr-targeted system containing miR29b liposome formulation resulted enhanced biological effects on the suppression of target gene's expression (efficient inhibition of Mcl-1 expression at the mRNA and protein levels) compared with the nontargeted or nonprotamine-containing liposomes [125]. Huang's group demonstrated efficient miRNA delivery using a tumor-targeted delivery system into experimental lung metastasis of murine B16F10 melanoma. They developed a liposome–polycation–hyaluronic acid nanoparticle system modified with a tumor targeting single chain antibody fragment (scFv) for systemic delivery [126]. Delivery of miR34a using this system demonstrated apoptosis, inhibition of survivin expression, and downregulation of the mitogen-activated protein kinase pathway in B16F10 cells. Systemic delivery of miR34a using this system significantly downregulated survivin expression in the metastatic tumor and reduced tumor load in the lung. Apart from using liposome systems, a number of groups have also worked on a polymer delivery system for the same purpose. One such example was using PLGA-based nanoparticles. PLGA was extensively studied for its ability to deliver different therapeutic agents. This polymer-based particles were shown to escape from the endosomal compartment to the cytoplasmic compartment and release their contents over longer periods of time. These features rendered PLGA particles as potential tool for efficient oligonucleotide or miRNA delivery. A group from China has modified the biodegradable PLGA nanoparticles with a polyplexed PEI coating in which the PLGA acts as the core and cationic PEI as the shell with an aim of encapsulating negatively charged nucleic acids. With the help of cationic shell, they efficiently encapsulated

miR-26a, a cell cycle suppressor, and demonstrated efficient delivery to human hepatocellular carcinoma cells such as HepG2 cells [127]. This significantly increased the expression levels of miR-26a and inhibited the cell cycle progression by induction of G1 phase arrest in transfected HepG2 cells. These PLGA nanoparticles also showed a better safety profile than PEIs and liposomes. In another instance, Sekar et al. [128] encapsulated chemically modified antagomirs in PLGA nanoparticles and showed efficient internalization and sustained release into cells. They also demonstrated tumor regression with the delivery of antagomirs. Their study results indicated that antagomir delivery is not only efficient in crossing cell membranes but also maintained the threshold of intracellular antagomir levels by its slow release profile for prolonged therapeutic effect.

A highly branched dendritic polymer including PAMAM has attracted interest as a nucleic acid delivery vector [129]. The presence of primary amine groups on their branched surface bind nucleic acids, compact it into polyplexes, and promote cellular uptake in wide variety of cultured cells. Primary amines on the surface also make it possible to conjugate suitable ligands such as transferrin for tumor or brain delivery. Overexpression of miR21 plays a key role in majority of cancers. Downregulation of miR21 therefore leads to repression of cell growth, increased cellular apoptosis, and cell cycle arrest, which can theoretically enhance the chemotherapeutic effect in cancer. Ren et al. [130] used this PAMAM dendrimer polymer as a carrier to co-deliver anti-miR21 and 5-fluorouracil to achieve delivery of miRNA to human glioblastoma cells and enhance the cytotoxicity of 5-fluorouracil (5-FU). With the help of positively charged primary amine groups, the miRNA gets encapsulated easily. Because of the presence of well-defined cavities and open architecture in PAMAM, guest molecules such as 5-FU get encapsulated into the macromolecular interior through hydrophobic interactions. Through their charge-based interactions, 5-FU-PAMAM could conjugate with miR21 [130]. With this system, the authors demonstrated significant improvement in cytotoxicity of 5-FU and a dramatic increase in the apoptotic percentage of U251 cells. They also showed that this co-delivery brought down the migration ability of tumor cells, suggesting that the co-delivery system may have an important clinical application in the treatment of miR21-overexpressing glioblastoma.

### 18.6.2 miRNA and Antagomir Delivery in Other Diseases

miRNA and antagomir delivery is also being used in number of diseases other than cancer. The development of antisense oligonucleotide-mediated (antimiR) knock-down and miRNA-mimic mediated overexpression are the techniques that are being followed. Researchers from University of California San Diego (UCSD) identified a new way to regulate the uncontrolled growth of blood vessels [131]. This uncontrolled growth often leads to vascular malformations and hemangiomas, which may become life threatening. The researchers found the switch mechanism that converts the normal blood vessels from the resting state to proliferative state and found a small miRNA (miR132) responsible for controlling the switch. They identified a complementary miRNA that binds to and neutralizes the original miRNA, thereby turning

**TABLE 18.1 MicroRNA Therapeutics in Development**

| miRNA Drug | Indication | Status | Company |
|---|---|---|---|
| let-7 mimic | Lung cancer | Preclinical | Mirna |
| miR-15 | Post-MI remodel | Preclinical | MiRagen, Inc. |
| miR-21 antagomir | Fibrosis | Preclinical | Regulus, Inc. |
| miR-33 antagomir | Cholesterol | Preclinical | Regulus, Inc. |
| miR-34 mimic | Prostate cancer | Preclinical | Mirna/Assuragen |
| miR-92 antagomir | Cardiovascular | Preclinical | MiRagen, Inc. |
| miR-122 antagomir | Hepatitis C | Phase 2 | Santaris A/S |
| miR-122 antagomir | Hepatitis C | Preclinical | Regulus, Inc. |
| miR-208 antagomir | Chronic heart disease | Preclinical | MiRagen, Inc. |
| miR-451 antagomir | Polycythemia | Preclinical | MiRagen, Inc. |

MI: myocardial infarction; miRNA: microRNA.

off the angiogenic switch controlling disease severity. A lipid-based, cyclic RGD-containing nanoparticle was designed to deliver miRNA or anti-miRNA to the diseased or proliferative blood vessels that express $\alpha v\beta 3$ [131]. The scientists also found out that by delivering more of this miRNA, it may be possible to promote new blood vessels development in patients who have sustained tissue damage from stroke, heart attacks, or diabetes.

Studies have shown that stroke alters expression levels of multiple miRNAs in neural progenitor cells. miRNA 124, a preferentially expressed miRNA in neurons has been known to be one of them. Liu et al. [132] showed that there was substantial reduction of miRNA 124 in neural progenitor cells after stroke and that this was inversely associated with activation of Notch signal [132]. This group efficiently introduced this miRNA124 into progenitor cells using a noncovalent peptide (MPG)–based nanoparticle system and demonstrated that this inhibited neural progenitor cell proliferation and promoted the neuronal differentiation of the progenitor cells [133]. MPG is a 27-residue-long primary amphipathic peptide that forms stable complexes with miRNA [133]. This peptide has three distinct domains, which arean N-terminal hydrophobic motif required for interaction with lipid moiety of cell membrane, a hydrophilic domain involved in the interaction with nucleic acids, and a linker domain that improves the flexibility and integrity of hydrophobic and hydrophilic domains.

Hwang and his colleagues used brain-targeted nanoparticles to deliver miR124a to brain [134]. They used the rabies virus glycoprotein (RVG)–labeled nontoxic disulfide linkage in branched polyethyleneimine (SSPEI) nanomaterial to deliver miR124a to neurons. This group has demonstrated enhanced accumulation of miR124a using a cy5.5-miR124a/RVG-SSPEI. One challenge of using this delivery system for miRNA delivery *in vivo* involves its passage through BBB and delivery of drugs to the CNS. Mannitol played a critical role in supporting BBB opening to facilitate RVG-SSPEI–mediated transport of the miRNA to the brain. So, after the role of specific miRNA in disease pathogenesis is established, selecting anti-miRNA or miRNA mimics and appropriate delivery strategies will be the next critical steps

for successful therapy. It is hoped that miRNA therapeutics with the help of an effective and safe delivery system will soon lead to effective treatments for undruggable targets. The biotech industries try to make the best of it by identifying miRNAs for appropriate therapeutic applications. Table 18.1 shows some of the miRNA mimics or antagomers listed by the companies, in preclinical and clinical development to substitute or downregulate overexpressed miRNA.

## 18.7 CONCLUSIONS

The discovery of RNAi-mediated gene silence heralds a powerful new strategy for treating human diseases. Despite the tremendous efforts from academia and industry in providing a glimpse of this breakthrough discovery in molecular biology, there still remains a great challenge in its clinical translation into viable therapies. Although there are several obstacles for successful RNAi therapeutics, a major hurdle is in overcoming the delivery barriers to the targeted tissue and cells without disrupting their effectiveness and trigging unwanted immune responses. Toward this end, we have discussed some of recent developments in solving some of the delivery issues for successful RNAi therapies *in vitro* and *in vivo*. Although each system has its own merits and shortcomings, multifunctional nanosystems have shown tremendous potentials for RNAi therapy. Thus, the further advancements in gene delivery research will greatly hinge on the continued progresses in conjugation and formulation technologies that can pave the way forward for the development of next generation of mature technologies for their successful clinical translation.

# Advent and Maturation of Regenerative Medicine

ABNER M. MHASHILKAR and ANTHONY ATALA

## 19.1 INTRODUCTION

The goals for regenerative medicine (RM) are focused toward developing innovative tools in modern medicine. Recent progress has led to the development and clinical implementation of newer technologies, ranging from diagnostics to therapeutics for a wide variety of metabolic, degenerative, and infectious diseases. These include specific applications toward age- and genetic-related human and animal dysfunctions and disorders.

The worldwide RM landscape is changing and rapidly evolving with novel technological advances emerging not only from research centers in North America, Europe, and Australia but also from translational, clinical, and manufacturing groups in Asia and Latin America. The focus of this review is to present, in a nutshell, the current status of adult stem cell therapy and tissue engineering (TE), including the challenges faced, progresses attained, and an optimistic view of the future. We will also provide our views on how the next 20-plus years will potentially affect these RM-driven innovations and how they are applied toward a variety of disease treatments, cures, and diagnostics.

## 19.2 REGENERATIVE MEDICINE: LOOKING BACK

After the breakthrough sequencing of the human genome a decade ago [1], personalized RM, including stem cell therapies and TE technologies, has generated an immense amount of interest, momentum, and hype. As a result, there has been an exponential increase in the expectations for translation of these technologies, both on a national and global scale. This is because RM offers potential solutions to many unmet clinical needs and challenges and provides a variety of innovative stem cell therapy and TE tools to repair, regenerate, and rebuild tissues and organs [2].

## 19.3 TRANSPLANTATION MEDICINE: HISTORICAL PERSPECTIVES

To date, the observational studies encompassing several decades have inferred that, unlike amphibians, which can regenerate limbs, humans react to injury via responses geared toward wound closure and healing and are thus unable to undergo similar regeneration processes. This healing process is further decreased by aging as well as the challenges associated with chronic, acute, and genetic diseases and dysfunctions [3]. In the 18th century, clinicians attempted organ transplantation procedures in animals and humans in order to replace tissues and organs that had been damaged by injury or disease, but the results were poor. In the early 1950s, the evolving fields of surgery and a new understanding of immune-suppression processes united to catalyze rapid advancement of transplantation medicine. After a string of many unsuccessful attempts, organ transplants became a reality (see Table 19.1, which represents a series

**TABLE 19.1 History of Organ Transplantation and New Related Procedures**

| Year | Organ or Procedure | Site or Professionals Involved |
|---|---|---|
| 1914 | Skin grafting | World War I |
| 1954 | Kidney | Brigham and Women's Hospital, Boston, MA |
| 1956 | Bone marrow transplantation | Dr. Donnall Thomas in a recipient twin |
| 1962 | Successful kidney | Drs. Murray and Hume at Brigham and Women's Hospital, Boston |
| 1963 | Successful lung | Dr. Hardy at the University of Mississippi Medical Center |
| 1966 | Pancreas and kidney | Drs. Lillehei and Kelly at the University of Minnesota, MN |
| 1967 | Liver | Dr. Starzl at the University of Colorado, Denver, CO |
| 1967 | Heart | Dr. Barnard, Groote Schuur Hospital, Cape Town, South Africa |
| 1968 | Heart—USA | Dr. Shumway, Stanford University Hospital, Stanford, CA |
| 1981 | Heart and lung | Dr. Reitz, Stanford University Hospital, Stanford, CA |
| 1983 | Single lung | Dr. Cooper, Toronto General Hospital, Toronto, Canada |
| 1983 | Cyclosporin | FDA approves cyclosporin, successful antirejection drug |
| 1984 | NOTA | National Organ Transplant Act authorizes OPSs |
| 1986 | Double lungs | Dr. Cooper, Toronto General Hospital, Toronto, Canada |
| 1988 | Viaspan | FDA approval, extends the preservation of donated livers |
| 1989 | First living-related liver | Dr. Broelsch, University of Chicago Medical Center, Chicago, IL |
| 1989 | Small intestine | Dr. Goulet, Paris, France |
| 1990 | First living-related lung | Dr. Starnes, Stanford University Medical Center, Stanford CA |
| 1993 | Xenografting baboon–human liver | Drs. Todo, Tzakis, Fung, and Starzl, Pittsburgh, PA |
| 1994 | Prograf (FK506) | Immunosuppression drug |
| 1995 | CellCept and Neoral | Formulation of cyclosporine with fewer side effects |
| 1998 | Hand | Drs. Owen and Dubernard, Lyon, France |
| 2005 | Partial face | Drs. Devauchelle and Dubernard, Amiens, France |
| 2010 | Full face | Barcelona's Vall d'Hebron hospital |

FDA: Food and Drug Administration; OPS.

of organ transplantation procedures successfully accomplished in the past 60 years). Breakthroughs included the first kidney transplant in 1954 between identical twins [4,5], the first liver and lung transplants in 1967 [6–9], and a pancreatic transplant in 1966 [10]. This work culminated with the first heart transplant in 1967 [11]. The field of kidney transplantation took a leap in the 1990s, when about 11,000 kidney transplants were carried out in 1996 alone. About 3000 of these involved kidneys recovered from living donors [12]. Transplantation of other organs such as the liver, heart, lungs, pancreas, and small bowel are now considered an accepted part of medical treatment. In addition, other breakthroughs, including bone marrow and corneal transplants, have been made [13]. In all of these cases, mature, fully functional organs were transplanted [14–17].

Another milestone in this process was the discovery of hematopoietic stem cells (HSCs). For the first time, a group of cells, rather than a fully functional organ, could be transplanted in order to "seed" the marrow and reconstitute all hematopoietic cells in the patient [18]. Other important medical breakthroughs in the past 20 years, such as tissue typing and the development of immunosuppressive drugs, have allowed for more successful organ transplants and longer survival times for transplant recipients [19,20]. The most notable development in this area was Jean Borel's discovery of an immunosuppressive drug called cyclosporine in the mid-1970s. This drug was approved for commercial use (in the United States) in 1983 [21,22].

Despite these significant milestones in transplant medicine and the tremendous impact they have had on many lives, the use of transplantation is limited because there simply are not enough organs to transplant [18]. Unfortunately, the need for organ transplants continues to exceed the organ supply, and more and more names are being added to the transplant waiting lists all around the world.

## 19.4 BONE MARROW TRANSPLANTATION AND HEMATOPOIETIC CELL TRANSPLANTATION

The past 60 years has seen the increased use of bone marrow and HSC transplantation to treat a variety of malignant and nonmalignant diseases. Early observations in radiation biology led to the finding that bone marrow is extremely sensitive to the damaging effects of radiation. However, it was subsequently observed that infusion of healthy marrow could rescue lethally irradiated animals. This led to the concept of destroying diseased bone marrow using whole-body radiation and subsequently rescuing the patient with healthy bone marrow to cure the disease. Some 200 allogeneic bone marrow transplants were performed in this manner in the 1950s, although there were no long-term successes until studies of transplantation using identical twin donors helped to illustrate the challenges associated with immune rejection and graft-versus-host disease (GVDH). These transplants spawned several effective research studies in the field [23]. The first successful bone marrow transplant procedures took place shortly thereafter in infants with X-linked lymphopenic immune deficiency and Wiskott-Aldrich syndrome [24,25]. These were followed closely by success stories in patients with aplastic anemia [26] and leukemia [27].

In 1988, the world's first umbilical cord blood transplant (UCBT) was performed successfully in a patient with Fanconi anemia. The cells used in this transplant were collected at the birth of the patient's sibling [28]. The 5-year leukemia-free survival rate in 503 children with acute lymphoblastic leukemia who received a transplant of umbilical cord blood (UCB) that was mismatched for either one or two human leukocyte antigens (HLAs) was similar when compared with the survival rate of 282 children who received bone marrow transplants [29]. In 1992, a patient was successfully transplanted with cord blood instead of bone marrow for the treatment of leukemia.

The limited number of cells in cord blood traditionally restricted its use to children and small adults. However, research into cord blood expansion and the use of multiple units for a single patient have allowed this cell source to become routinely available to many more patients. Over the past decade, the use of cord blood has rapidly expanded, and there has been a scientifically based realization that cord blood is an effective alternative for bone marrow. Advantages of cord blood appear to include a shorter procurement time, fewer issues with GVHD, and a smaller number of cells needed to obtain engraftment [30–32]. Despite considerable earlier skepticism initially by both scientists and clinical specialists in the field, UCB has now become one of the most commonly used sources of HSCs for allogeneic transplantation. Today an estimated 600,000 UCB units have been banked, and 20,000 UCB units have been distributed worldwide for both adults and children with life-threatening malignant and nonmalignant diseases. Table 19.2 gives a historical perspective on cord blood and its diverse applications and shows the exponential rise in cord blood banking worldwide [33–36].

Umbilical cord blood banks (UCBBs) have been established for related or unrelated UCBT. The progress in the field of UCBT has paralleled the huge interest in establishing and developing CBB worldwide. Today more than 400,000 cord blood grafts are available in more than 50 CBBs (http://www.bmdw.org and http://www.wmda.org). This development is due to the organization of international registries for outcome data collection such as the National Marrow Donor Program (NMDP; http://www.nmdp.org) [37]; the Center for International Blood and Marrow Transplant Research (CIBMTR; http://www.cibmtr.org); and other CBB networks, including Netcord (http://www.netcord.org) and Eurocord (http://www.eurocord.org), which is an international registry operating on behalf of the European Blood and Marrow Transplant (EBMT) group and includes European and non-European centers.

The NMDP, the largest donor registry, has facilitated unrelated donor hematopoietic cell transplants for more than 30 years. These unrelated donor bone marrow transplants have been used in both children and adults with acute leukemia, with roughly 10,000 recipients to date. Around 300,000 cord units are currently stored in banks worldwide. The NMDP contains typing information on more than 4 million potential donors and can search international registries as well. Bone Marrow Donors Worldwide (BMDW) is a collective database of 59 registries in 43 countries and 37 cord blood registries from 21 countries; 11,386,999 potential donors and cord units were available as of July 2007 [37–40].

**TABLE 19.2 Historical Perspective on Cord Blood Banking and Applications [30–32]**

| | |
|---|---|

| 7. Development of cord blood banks (CBB) (related and unrelated use | Paris, Dusseldorf, New York, and Milan |
| 8. Creation of the Eurocord Netcord network | Wernet (2004) |
| 9. Compared to matched, unrelated bone mismatched cord blood gave similar long-term leukemia-free survival in children | Rocha (2001–2004) Takahashi (2007), Eapen et al. (2007), and Laughlin et al. (2004) |
| 10. Improvement of results mostly in adults by double cord blood transplants and nonmyeloablative conditioning regimens | Hwang et al. (2007) |
| 11. Isolation of nonhematopoietic stem cells from cord blood as a first step for RM | Kogler et al. (2004) |
| 12. Development of cord blood banks | Worldwide |

The largest UCBB in the United States is the New York Cord Blood Bank, which has collected more than 35,000 units. The UCBB in Spain now has more than 28,000 specimens collected and processed, and the Australian cord registry has more than 18,000 specimens. Several additional UCBBs are organized throughout the United States, Europe, and Asia, which are collecting units much like a blood bank solicits volunteer blood donations. Also, as a stand-alone example, Taburit (http://www.taburit.org) is a successful UCBB company based in Israel and has banked 3000 units to date.

In addition to bone marrow and cord blood, peripheral blood stem cells (PBSCs) have gained popularity as a source of stem cells since their initial introduction in the 1980s [41]. Over the past 40 years, HSC transplantation has been well established as a therapeutic option against inherited disorders [42–44]. This was soon followed by the identification and definition of autologous [45,46] and allogeneic [47,48] approaches when further developments in HLA typing [49,50] and supportive care were made, and this has led to changes in the available sources of stem cells in the past 30 years. Transplants using PBSCs are not described at length in this chapter, but further information can be obtained through several other resources, including the references provided earlier.

Also, it is worthwhile to mention that many new businesses are on the rise using private, for-profit, UCBBs, which often solicit funds from expectant mothers to pay for the collection and storage of cord blood after delivery. Apart from UCBBs, several additional new banking that have sprung up in this field, including those that store adipose cells, placental cells, dental cells, and several other cell types.

## 19.5 EMERGENCE OF STEM CELL THERAPY

Stem cell therapy falls under the umbrella of RM and is fast emerging as an innovative way to treat a variety of diseases and repair a large number of injuries. It provides enhanced scope to tackle many degenerative diseases caused by the premature death or malfunction of specific cell types and the body's failure to replace or restore them. The cell therapy industry has grown exponentially and is now international in scope, representing $1 billion dollars per year turnover, and includes multifaceted technologies and therapeutics ranging from tissue and organ transplantation to advanced stem cell therapies, including TE and organogenesis. Readers are invited to study Tables 19.3 and 19.4, which represent stem cell research

**TABLE 19.3 Historical Perspective on Stem Cell Research Independent observations by the authors and also through several other search directives including http://stemcellhistory.com/.**

| Year | Findings |
|---|---|
| 1950 | First animals made by *in-vitro* fertilization (IVF) |
| 1960 | Teratocarcinomas determined to originate from embryonic germ cells in mice |
| 1960 | Embryonal carcinoma cells (EC) identified as a kind of stem cell |
| 1960s | Phenomenon of neurogenesis in human adults shown by Altman and Das |
| 1968 | The first human egg is fertilized *in vitro* |
| 1970 | EC cells injected into mouse blastocysts make chimeric mice |
| 1970 | Cultured SC cells are explored as models of embryonic development in mice |
| 1974 | Toronto scientists James Till & Ernest McCulloch establish the foundation for stem cell science |
| 1974 | 93rd Congress bans all federally funded fetal tissue research |
| 1974 | National Commission |
| 1975 | Protection of human subjects of biomedical and behavioral research |
| 1975 | Ethics Advisory Board established for fetal and fetal tissue research that originate from abortions |
| 1978 | First IVF baby is born in England |
| 1978 | Hematopoietic stem cells shown in cord blood |
| 1981 | Mouse ES cells are derived from the inner cell mass of blastocysts |
| 1981 | Mouse ES cells are grown *in vitro*. ES cells injected into mice form teratomas |
| 1984 | Pluripotent, clonal cells called embryonal carcinoma (EC) cells are developed |
| 1988 | When exposed to retinoic acid, these cells differentiate into neuron-like cells and other cell types |

**TABLE 19.3** (***Continued***)

| Year | Findings |
|---|---|
| 1988 | Federal Panel approves funding of embryo research |
| 1989 | A clonal line of human embryonal carcinoma cells derived yielding tissues from all three germ layers |
| 1990 | President George H.W. Bush vetos bill |
| 1993 | President Clinton Executive Order lifts moratorium and reverses order |
| 1994 | Human blastocysts are generated and the inner cell mass is maintained in culture |
| 1994 | ES-like cells form in the center and retain stem cell-like morphology |
| 1995 | Congress bans federal funding for research on embryos through Dickey-Wicker Amendment |
| 1995 | Nonhuman primate ES cells are maintained *in vitro* from the inner cell mass of monkeys |
| 1998 | James Thomson isolates human embryonic stem cells |
| 1999 | HHS legal opinion OKs research on hESC lines |
| 2000 | Scientists derive human ES cells from the inner cell mass of blastocysts |
| 2000 | ES proliferates *in vitro* and form all three germ layers and teratomas in immune-deficient mice |
| 2001 | President Bush prohibits federal funding of human embryonic stem cell research |
| 2004 | President's council on bioethic: "Monitoring Stem Cell Research" |
| 2004 | California Institute of Regenerative Medicine (CIRM): Prop. 71 worth $3 billion for 10 years |

| 2007 | New National Academies guidelines |
| 2007 | President Bush calls for work on alternate sources |
| 2007 | Yamanaka and Thomson independently derive iPS cells |
| 2008 | Only 16 of 21 lines eligible for federal funding were ethically derived |
| 2008 | NAS release new guidelines |
| 2008 | ISSCR releases guidelines for clinical translation |
| 2009 | President Obama reverses 2001 Executive Order |
| 2010 | Geron initiates clinical trial of human embryonic stem cell-based therapy |
| 2010 | Advanced cell technology wins FDA approval to test stem cell therapy for degenerative eye disease |
| 2011 | Geron discontinues clinical trial |

and development and the commercial products available, respectively. Cell therapy has also been designated as a disruptive technology [51] with its evolving roots in blood transfusion, bone marrow and organ transplantation, tissue banking, and reproductive *in vitro* fertilization. Cell-based therapies have progressed from the first recorded human to human blood transfusion by James Blundell (Guy's Hospital, London, UK) through to the advanced cellular therapies of today. This has been a 200-year journey based initially on clinical trial and error and only recently has

**TABLE 19.4 Current Approved Stem Cell-Based Commercial Products Compiled by the authors.**

| Company | Product | Product Information |
|---|---|---|
| Advanced BioHealing-Shire), CA | Dermagraft | Human fibroblast—dermal substitute |
| Altrika, UK | MySkin, Cryoskin | Allogeneic keratinocytes scaffold |

extensive progress been made through laboratory sciences. These scientific studies have provided further understanding, newer values, and unique challenges to justify this field as a stand-alone distinct industry. The variety of cell therapeutics and translational technologies is expanding rapidly and currently is highly diversified and following broad-based approaches. The number of different types of cells used for therapies is also rapidly expanding, and the future holds even greater promise. In just 2009, the market for cell-based therapies in the United States was targeted toward about 100 million patients for indications including heart disease, diabetes, neurodegenerative diseases, and musculoskeletal disorders. It has been estimated that this field would generate more than $2 billion by 2012 and will generate more than $5 billion by 2014.

## 19.6 EMERGENCE OF TISSUE ENGINEERING AND SCAFFOLDS

As recently as the early 1980s, the term "tissue engineering" was loosely applied to the use of prosthetic devices and the surgical manipulation of tissues. That decade also saw the inaugural Keystone meeting in Colorado titled "Tissue Engineering," which was sponsored by the National Science Foundation. Boston was the birthplace of dedicated TE focus that combined the principles of biomedical engineering with biological sciences such as cell and molecular biology. The term "tissue engineering" was actually coined in a publication titled, "Functional Organ Replacement: The New Technology of Tissue Engineering" in *Surgical Technology International* in 1991 [52]. TE is the regeneration of biological tissue through the use of cells or biological scaffold materials (or both), and it offers the potential to create a paradigm shift in medicine. The goal is to develop new forms of therapy that allow the repair or regeneration of cells, tissues, and organs that have lost their function because of diseases, injuries, or age- or genetic-related defects. Potential applications of TE include protocols for bone; cartilage; soft tissue; skin; cardiovascular; neuronal; and other tissues such as bladder, kidney, liver, lungs, and others [53–55]. Parallel scientific advances in biomaterials, stem cells, growth and differentiation factors, and biomimetic environments have helped us to generate tissues in the laboratory from combinations of engineered extracellular matrices ("scaffolds"), cells, and biologically active molecules.

Combining stem cells with scaffolds was shown to be a viable approach for engineering tissues and for effective cellular delivery. In 1987, the word "biomaterial" was coined and defined as "a non-viable material used in a medical device, intended to interact with biological systems" (European Society of Biomaterials Conference, 1987). The field has advanced considerably since that time, and a series of innovative implantable scaffolds created with a wide variety of specific biomaterials have been developed. Such scaffolds are currently being explored to promote the viability and regulated differentiation of stem cells, and their role is to provide a structural base for regenerating tissue with the tensile compliance required for the planned implantation environment. The next paragraphs will briefly review the most commonly used scaffolds (also see Table 19.5, which

**TABLE 19.5 The World of Scaffolds and Processing Technologies**

| Natural Scaffolds | Artificial Scaffolds |
|---|---|
| Collagen, fibrin, fibrion, silk, agarose | Polyglycolic Acid (PGA), Poly (lactic acid) (PLA) |
| Glycosaminoglycans (GAGS), HA | PLGA, PLLA, PDLA, PDLLA, Poly(e-caprolactone) |
| Chitosan, Alginates, Agarose, Starch | Polyurethanes, Polymethanes, Polyorthoesters |
| Keratin, Decellularized organs/grafts | Polyanhydrides, ceramic, hydroxyapatites |

| Scaffold Processing: Modulating Scaffold Structure, Mechanical Tensile Strength, Permeability, and Porosity Features | | |

| Selective Laser Sintering (SLS) | Stereolithography | Shape Depositing Manufacturing |
| Robotic Microassembly | Decellularization | |

lists different types of scaffolds and the processing methodologies currently used to create them) [56].

Many interesting studies worldwide make use of the ”scaffold and cells” method of TE. These include examples of bioartificial liver devices (using living hepatocytes), an artificial pancreas, an artificial kidney, and artificial bladders. This approach is also used to engineer cartilage, bone, skin, heart valves, and trachea, to name a few. A wide range of biomaterials, including both natural and synthetic biomaterials and scaffolds, has been developed for different applications [56].

Scaffolds constructed from natural materials include different derivatives of the naturally occurring extracellular matrix (ECM) proteins, such as collagen, fibrin polysaccharide–derived materials, chitosan, glycosaminoglycans, hyaluronic acid, and others. Collagen (which can be isolated from a variety of tissues, such as skin, tendon, or bone, and is usually of animal origin) has been shown to effectively support the culture of some stem cells, such s human mesenchymal stem cells derived from different tissues, and several proof-of-concept studies have been performed for a variety of applications, including engineering bone, ligaments, and cartilage [57,58]. Fibrin, which is derived from the enzymatic cleavage of fibrinogen by thrombin, is associated with a huge body of work describing the effective use of fibrin-based scaffolds in a variety of applications [59–61]. Another protein that has been investigated for use in generating tissue-engineered scaffolds is silk. Alternatively, silk fibroin has been shown to have a slower degradation rate than silk itself as well as desirable mechanical properties for engineering bone, cartilage, and ligament tissues [62,63]. Peptide-based biomaterials consist of short sequences of amino acids, which can produce self-assembling scaffolds. These scaffolds can potentially combine the functionality of protein-based scaffolds by using motifs derived from naturally occurring proteins with the reproducibility of synthetic scaffolds. Many of the peptide-based biomaterials can self-assemble into three-dimensional (3D)

scaffolds through the use of amphiphilic peptides. In addition, peptide-based scaffolds have been used for cell 3D cultures of neural stem cells (NSCs), and these constructs have served as intramyocardial microenvironments for endothelial cells, neurite outgrowth, and active synapse formation [64–66]. Finally, the polysaccharide-based biomaterials include agarose, alginate, hyaluronan, and chitosan, which have also been used for the culture and differentiation of stem cells [67–69].

Several synthetic biomaterials are currently used in a number of TE applications, and these provide an alternative to natural materials for the culture of stem cells and provide effective platforms for TE. The most commonly used synthetic materials, as seen in Table 19.5, include polyglycolic acid (PGA), poly(lactic acid) (PLA), polycaprolactone (PCL), and several other derivatized copolymers that have been shown to have a wide variety of applications in different TE models [70–73]. There are also the ceramic-based biomaterials, including bioactive glass and hydroxyapatite, a naturally occurring ceramic material. A synthetic version of hydroxyapatite hydrogel has also been investigated for use as a potential replacement for bone tissue because of its strength and biocompatibility [74–77].

Another scaffold material under intense investigation is acellular matrix, which is derived from the decellularization of various tissues. To create these, the cellular remnants are removed from an organ, leaving behind the ECM. This approach is attractive because the resulting matrix is similar or identical to that found in natural tissue in terms of topography, composition, microstructure, and biotensile properties. Decellularized matrices maximize the regeneration of both the structural and functional aspects of tissues and organs. Simple tissues as well as complicated organs have been decellularized, and optimized protocols have been developed to completely remove the cellular components while keeping the ECM intact [78–83]. Table 19.5 lists various processing approaches to formulate these scaffolds, but detailed descriptions of each of these processes are beyond the scope of this review. Nonetheless, it is worthwhile to mention the production of nanofiber scaffolds via electrospinning because more and more innovative scaffolds are being created using this method because it provides better biocompatibility, mechanical properties, porosity, permeability, and environment-specific compatibility [84–86].

The examples described here illustrate the importance of the extracellular environment in determining cell behavior in order to preserve function, survival, viability, and potency. However, as a result of both successful and unsuccessful trials in the field, the TE industry has benefited from a heavy dose of reality, and a number of lessons have been learned. Each of the above-mentioned scaffolds presents its own sets of advantages and disadvantages, and none are free of drawbacks at the present time. Several groups are further fine tuning biological scaffolds toward effective therapeutic use [87].

## 19.7 REGENERATIVE MEDICINE: LOOKING FORWARD

Health care management is constantly evolving, and continuous debates are ongoing on a global scale to manage care in both developed and developing countries. These

discussions have resulted in changes that have actually led to better health care, but the increased survival and lifespan resulting from these changes have led to an increase in the prevalence of diseases associated with aging. Many significant human diseases arising from the loss or dysfunction of specific cell types in the body, such as Parkinson's disease, diabetes, and cancer, are becoming increasingly common. In a remarkably short span of time, stem cells and the RM field have attracted an extraordinary level of interest from scientists, clinicians, industry, and the general public. The advances in the field and potential applications of stem cell research findings in RM are truly turning into global enterprises. Clinical translation of RM-based technology is now the key focus of several groups whose goals are the scientific advancement and practical therapeutic applications for the benefit of patients worldwide. This complex translational pipeline requires the interplay of research investigators, operational experts, investors, and clinicians who can work closely, and discussions with regulatory agencies within the organization, state, and federal (Food and Drug Administration [FDA]) levels; patient advocacies; ethics committees; manufacturing operations; and logistics are required for effective planning and higher quality successful outcomes.

Stem cell research and RM offer unique opportunities for developing new therapeutic approaches to prevent and treat these debilitating and life-threatening diseases, and they also provide new ways to explore fundamental questions of biology. The current optimism over potential stem cell therapies is driven by new understandings of genetics and developmental biology. Gradually, the curative and regenerative potential that lies in harnessing stem cells is being realized as the clinical applications of adult stem cells are investigated and used in the treatment of cancer; autoimmune, metabolic, and organ-related diseases; immunodeficiencies; and multiple age- and genetic-related anomalies.

## 19.8 CELL THERAPY, TISSUE ENGINEERING, AND THE GLOBAL LANDSCAPE OF REGENERATIVE MEDICINE

### 19.8.1 Stem Cell Therapies

Stem cell therapies are a new medical frontier. Currently, innovative work is being carried out on a global scale, and in some cases, the resulting therapeutics are already benefiting patients. These therapies involve a variety of adult progenitor cell types from a variety of tissues, including bone marrow, umbilical cord, umbilical cord matrix (Wharton's jelly), peripheral blood, adipose, amniotic fluid, placenta, endometrium, tooth pulp, eye limbus, hair follicles, and many other sources. The field is currently in its infancy, and as a result, it is facing challenges, including fragmentation, as studies with similar goals and approaches have shown that the variability in cell type production and effectiveness is not easily evaluated. However, recent research has validated multiple alternative sources of pluripotent stem cells, and this has led to a rapid development of adult cell reprogramming that has made this approach much safer for patients and brought the hope of pluripotent stem cell

**FIGURE 19.1** Clinical trials with mesenchymal stem (stromal) cells (MSCs). (a), Tissue types used in MSC trials. (b), Different phases of MSC trials. therapeutics much closer to a practical reality. As an example, Figure 19.1 depicts the number of ongoing trials using mesenchymal stem cells from different tissues and their results. Cell sources, clinical stage, and targeted indications (Table 19.6) are also presented.

As depicted in Figure 19.1 and Table 19.6, the number of different diseases and dysfunctional areas that are being targeted with cell and tissue therapy is also growing quickly, but there are several areas, including cardiovascular, orthopedic, and neuronal disorders as well as GVHD and diabetes, that are being investigated in a more aggressive format. Table 19.7 gives a glimpse of clinical studies being pursued in just the neurologic arena using both neuronal and non–neuronal-derived stem cells [88,89]. NSCs, their progenitors, and differentiated cell derivatives along with other stem cell–based clinical strategies have steadily moved forward to target central nervous system (CNS) diseases and injuries. Current phase I and II trials using stem cells in the CNS are the vanguard for the widely anticipated next generation of regenerative therapies and as such are pioneering the stem cell therapy process [88].

Stem cell science is extraordinarily promising. There have been great advances in treating diseases and conditions of the hematopoietic system using blood-forming stem cells, and these show us just how powerful stem cell therapies can be. Scientists

all over the world are researching ways to harness stem cells and use them to learn about, diagnose, and treat various diseases and conditions. Every day, scientists are working on new ways to shape and control different types of stem cells in ways that are bringing us closer to new treatments. Many potential treatments are currently being tested in animal models, and some have already been brought to clinical trials. There is tremendous optimism that stem cell therapies will someday be available to treat a wide range of human diseases and conditions. The future is bright in this industry, and global groups are focused on achieving several curative milestones in the field. They are also developing stem cell–based therapies for effective disease management, immunomodulation, cosmetic, bioaesthetic, and effective drug delivery functions. Some specific examples of areas of current research in RM include projects such as replacement of skin for burn patients and patients with nonhealing wounds, pressure sores, or diabetic foot ulcers. There is also tremendous interest in bone and cartilage regeneration; bladder repair; vascular TE; nerve regeneration;

**TABLE 19.7 Application of Human Stem Cells for Different Human Neuropathies**

| Group/Company | Type of Study/Indication | Type of Cells |

restoration of peripheral nerve or spinal cord after injury; restoration of the cells of the CNS after tumor resection, disease, or injury; and regeneration of pancreatic tissue to produce insulin. By all measures, we are quickly entering a new era in the treatment of disease and injury: the era of stem cell therapies. Progress in this field was initially slowed because the use of embryonic stem cells raised serious ethical issues regarding the destruction of embryos and often gave rise to cancer and other side effects. Since the discovery of adult stem cells, research has moved forward at an accelerated pace and continues rapidly in all directions.

### 19.8.2 Tissue Engineering

Tissue engineering and cell therapy comprise a market for regenerative products that is expected to grow in the United States from $9.9 billion in 2011 to almost $32 billion by 2018 [90]. This market spans many specialties, the biggest of which are orthopedic and spine applications, cardiac and vascular disease, a wide range of neurologic disorders, diabetes, inflammatory diseases, and dental injuries. Competition in the field of TE and cell therapy is intense, with new companies being founded every day. The current industry focus is on disease areas that have the most patients and the largest unmet needs. These include cancer therapies, diabetes, orthopedics, and cardiovascular products, although several groups are also focusing their studies on diseases with smaller patient populations and a less crowded playing field, including Alzheimer's and Parkinson's diseases, multiple sclerosis, other neurodegenerative diseases, and ophthalmology. Key factors expected to influence the market for RM are continued political actions; venture capital; private equity and endowment funding; government funding; and particularly, positive clinical trial results. In addition, industry, pharmaceutical involvement, and investments and an increasing awareness among both physicians and the general public are driving this market. Several technologies in this segment, such as bone and skin grafts, are already being marketed. Growth in these markets will be sustained as the population ages and continues to require these products. Applications of RM in cardiology and vascular medicine will also be developed, and these will be rapidly adopted into clinical practice over the next decade. These include treatments of coronary artery disease, myocardial infarction, congestive heart failure, dysfunctional heart valves, peripheral vascular disorders, and abdominal aortic aneurysms [51,91–93].

However, challenges persist with interfaces between tissues and devices, including approaches intended to improve biocompatibility and integration between cells and novel devices, materials that self-assemble within the body, the fate of biomaterials and implant materials within the environment of the body, and optimal interaction between cells and the morphology and topography of surfaces and coatings. Also, there is a continuous need to look at newer varieties of synthetic scaffolds that are more effective in promoting 3D cell growth and vascularization and that provide a structure for effective assembly in a biofunctional tissue (or ultimately an organ). Possible features of novel materials include multiple characteristics, including the ability to react to external inputs in a controlled manner, the ability to attract endogenous progenitor cells using molecular and chemical cues, and the

ability to react and adapt to changes in physiological parameters. In addition, a number of studies have been designed to determine the optimal porosity and permeability of biomaterials, which facilitate vascularization and innervation of the new tissue with suitable mechanical integrity. Key scientific hurdles still remain in cell therapy and TE, such as graft rejection, and attempts to make the product less or nonimmunogenic are underway. In terms of replacement organs, new organs could be made outside the body or grown within the body. The latter situation may be more achievable. Regardless, creating entirely new organs remains challenging, although replacement hair, skin, teeth, and pancreatic islets may be achieved in the next 10 years, and the kidney is likely to be the first major organ to be created outside the body [51,91–93].

## 19.9 GLOBAL REGENERATIVE MEDICINE AND MEDICAL TOURISM

The current financial crisis has brought economic tightening and challenges raising capital for many industries, including the global RM landscape. This includes nonprofit and for-profit biotech groups and organizations. The health care business around the world is also changing as less expensive options for treatment are provided and cost and time-effective offshore locations for clinical trials and manufacturing are developed. The forces that are shaping the evolution of health care also include integration of worldwide personalized medicine with a lower cost and higher quality of care provided by accredited personnel and institutions that are supported by reliable and transparent information technologies. This rapidly changing environment is driven by unmet clinical needs, with the United States as the largest market trailed by Japan and Europe. In terms of growth, Europe is projected to march ahead of other world markets, propelled by renewed activity in Germany, the United Kingdom, and Belgium, among others [94,95].

Regenerative medicine is touted as the next-generation revolutionizing mode of modern medicine. Active support of governments around the world and technological breakthroughs are expected to result in high growth for the RM industry in the near future. RM also has the potential to emerge as one of the largest drivers of growth for the global economy. The global aging population is plagued with various age-related dysfunctions, and this population provides a readily available market for novel therapies based on stem cell therapy, TE, and various other tools of RM. Unlike other industries, the RM industry has reached its present stage mainly through private participation, but now that trend is changing as government and endowment funding is on the rise. China has set up a US$1.0 billion fund for research into this field. Other major players, such as Australia, India, Brazil, Argentina, South Korea, Singapore, and Malaysia, have been obtaining active support from their respective governments through funding or beneficial policies. The US government support mechanism for RM-driven technologies is the highest in the world, and it includes multiple federal and state-run granting mechanisms.

It can be a difficult process to ensure that policies reflect the desire for progress in disease management while maintaining the collective views of a country. For

example, research on stem cells is still fraught with ethical issues, both within and among nations. The alterations in policy that are occurring around the world clearly reveal a belief in the exciting therapeutic potential of RM, but this is coupled with moral criticisms of the investigation into the stem cell [94].

Big pharma, after maintaining a long-term watching stance, is also gradually investing in RM biotechnologies, indicating a significant, although slow-paced, shift in attitude. Much of the concern surrounding corporate investments was due to an abundance of unproven clinical trial data and the ethical implications associated with this type of research. With more phase I and II clinical trials advancing to later phases, big pharma is now showing more interest in RM. A distinctive prototype is Athersys, which entered into a global agreement with Pfizer ($6 million in initial research funding and $105 million after reaching the first commercial milestone) to develop and market its MultiStem technologies designed to treat inflammatory bowel disease, acute myocardial infarction, and GVHD. Cephalon (now Teva) made a deal to acquire a 20% stake in the Australian RM company Mesoblast, which is currently in phase II trials of its leading cardiovascular treatment product, Revascor. This alliance focuses on commercializing the adult stem cell products used to treat degenerative CNS and cardiovascular conditions. Obtaining worldwide rights for specific Mesoblast products, Cephalon fronted $130 million, with another $220 million to follow. More big pharma companies are trying to develop or obtain approaches of targeting, acquiring, and initiating RM programs.

According to New Global Industry Analysts, Inc., global investments in adult stem cells research are forecast to reach US$2.4 billion by the year 2015. Technological advancements, the rising number of research groups engaged in stem cell research activities, the broadening of these activities, and substantial investments from governments in leading global markets are the key factors driving growth in stem cell research worldwide. Additionally, the market is driven by the rising incidence of life-threatening diseases, large unmet needs in medicine, and the rising costs of drug development.

Despite the common economic downturn, there are signs that RM industry continues to grow in different parts of the world. Manufacturing, clinical studies, and so-called "medical tourism" with the aim of obtaining access to stem cell and tissue-engineered products are on the rise in areas such as China, India, South Korea, and Thailand. Using India as an example, hundreds of patients are now streaming into stem cell therapy clinics all over India even though there is still a big gap between the reality and the future potential in the field worldwide. In India, more than 25 public and several private research institutions are authorized to conduct stem cell research. The only stem cell therapy treatment tried and tested so far is bone marrow transplantation, allowed by the Indian Council of Medical Research. One reason for the fuss and hype surrounding stem cell therapy is its potential to address a plethora of medical conditions. Nevertheless, several hospitals and clinics across major cities in India have treatments for neuronal, cardiac, and reproductive areas of medicine, the largest number being in CNS diseases and soft tissue repair. In 2007, India brought out a set of guidelines for conducting stem cell research, but the

guidelines are not legally binding and have no power to curb clinical implementation of stem cell therapy. The situation is changing now as the government is intervening and underlining policies for RM registration and clinical trial practices. Fifteen clinical trials have been officially registered so far, and efforts have been implemented to curb or stop unregistered work. India has taken up the challenge, and the next 5 to 10 years will be the most defining period for the nascent stem cell industry in India, as the National Apex Committee for Stem Cell Research and Therapy (NAC-SCRT) has been set up by the Union Ministry of Health. This is a stepping stone for the Indian industries, entrepreneurs, and companies to take stem cell research and cell-based therapies to next level. The development of the NAC-SCRT has been very timely in India, and it will play a crucial role in fostering cooperation and productivity from the emerging new companies in the stem cell industry. This should serve as a good model for other international programs in southeast Asia and Latin America (Inter Press Service, India, 2011).

## 19.10 REGULATORY HURDLES

As discussed earlier, medical tourism to obtain unproven, nonlegalized, and unregulated RM technologies is a big problem not just in India but also in other attractive medical touristic sites in Eastern Europe, Latin America, the Middle East, and southeast Asia. These areas must be regulated, and the United States has implemented several initiatives similar to the ones followed by the Indian government.

The FDA recently acknowledged that clinical research has become increasingly global and issued guidance to help sponsors demonstrate that foreign clinical trials conformed to good clinical practice (GCP) standards and the agency's regulations, especially groups that did not conduct their foreign trials under an Investigational New Drug Application (IND). The guidance, *FDA Acceptance of Foreign Clinical Studies Not Conducted Under an IND Frequently Asked Questions*, follows up on a final rule (21 C.F.R. §312.120) issued in April 2008 (7 MRLR 262, 5/7/08) that made good GCP the standard of compliance for foreign clinical studies that are not being conducted under an IND, thereby replacing the Declaration of Helsinki the principles in the regulations. Although sponsors are not required to conduct foreign clinical studies under an IND, they must ensure that the study meets all the rule's requirements to use the study as support for an IND or application for marketing approval. The final rule requires review and approval by an independent ethics committee and informed consent from subjects along with ethical and data integrity standards for clinical studies, which appeared in the *Federal Register* (73 Fed. Reg.22800,4/28/08MedicalResearchLaw&PolicyReport).

The International Society for Stem Cell Research (ISSCR) and the International Society for Cellular Therapy have taken a critical position regarding "stem cell tourism" and unregulated commercial "cell therapies" around the world by launching guidelines dedicated to tracking commercial clinics and providing recommendations for stem cell therapy seekers that emphasize the following key points: (1) there are

several adult tissue types of stem cells with limited potentials to regenerate, (2) one type of cell therapy will not work on a wide variety of conditions, (3) there are very few accepted stem cell therapies, (4) clinics advertising through ad-hoc patient testimonials are suspicious, (5) a regulated and effective cell therapy process takes scientific innovation and a longer time, (6) a treatment is not necessarily safe even if it is autologous, and (7) an experimental treatment offered for sale is not the same as a clinical trial and can just be an expensive gouging of desperate patients. Responsibly conducted clinical trials are critical to the development of new treatments because they allow us to learn whether these treatments are safe and effective. The ISSCR supports participation in responsible clinical trials after careful consideration of the issues highlighted on its site (http://www.iscr.org) and after discussion with a trusted and accredited physician (or physicians).

Tissue-engineered and RM product development processes are often combinations of cells, scaffolds, and other factors and are complex in both structure and function. This introduces challenges for product developers to establish efficient manufacturing and characterization techniques to ensure that these products are safe and effective before clinical trials are conducted in humans. It is critical for early stage RM product developers to establish an FDA dialogue and relationship for their valuable feedback and advice highlighting key scientific considerations for strategic planning applicable specifically to their products [96].

Other critical components for effective development of RM therapies, not included in this review, pertain to establishment of proof of concept, statistically relevant preclinical animal (*in vivo*) studies, intellectual proprietary protection, optimization of process development, current good manufacturing practices, and building a clinical team to conduct the planned study in a cost-effective manner. These are all important pieces of the developmental puzzle needed to overcome translational barriers. Also, a worthwhile effort will be to develop clinical companion tools and diagnostic means that can evaluate the functional efficacy of the therapeutic modality in a clinical setup.

It has been 13 years since the discovery of human embryonic stem cells (hESCs). Companies such as Geron and Advanced Cell Technology (ACT) were leading multiple clinical programs, but unfortunately, Geron's hESC program to treat spinal cord injury was discontinued, and continual challenges in the hESC translation field remain because of ethical and practical issues with these cells. However, a preliminary report from ACT was published describing hESC-derived retinal pigment epithelium cell transplantation into patients with age-related macular degeneration with no signs of hyperproliferation, tumorigenicity, ectopic tissue formation, or apparent rejection after 4 months [97].

It is also worth mentioning the growing field of cancer stem cells (CSCs). Many groups currently aim to identify specific biomarkers of CSCs, especially the ones that play important roles in metastasis and tissue- or organ-specific invasion. Other features of CSCs are that they are highly tumorigenic and pluripotent and have the ability to self-renew. Many CSCs have been shown to possess multidrug resistance capacities, and they likely play a role in cancer relapse [98]. Further study of these cells will also help in devising new anticancer therapeutics in the near future.

## 19.11 THE FUTURE AND CHALLENGES

The RM product pipeline will hopefully open new venues and alternatives to organ transplantation for Americans on chronic mechanical and extracorporeal therapies. The field is continuously growing. Baby boomers will nearly double the number of Americans older than age 65 years by 2025, and the number of Americans without health care insurance will exceed 18% by 2015. US health care expenditures on treatment of acute illness, chronic illness, and long-term support of individuals in chronically debilitated states may double from $3 to $6 trillion, thus approaching 40% of US gross domestic product (GDP). If stem cell–based tissue regeneration enhances quality of life for aging Americans, potentially $3 to $5 trillion dollars of the US GDP can be redirected.

The RM field has evolved significantly in the past 15 years. We are now at a point where it appears that this industry will play a significant role in how we treat a range of diseases in the future. Major corporations such as Pfizer, Teva, Roche, Sanofi, Novartis, and Johnson & Johnson have created internal RM programs and are actively forming collaborations with researchers and companies in the field. Although a key focus for the field remains the need to demonstrate clinical efficacy through execution of large, well-designed clinical trials necessary to gain market approval, an equally important challenge is developing commercialization models for how RM will be delivered to the general population in a cost-effective way. The other evolving component for future growth in the field will be the development of efficient, effective product development and commercialization strategies.

To build tissues and organs, scientists are now beginning to understand the complexity of the many ways tissues can interact with each other. To achieve the envisioned goals of RM, a strong federally directed initiative is needed and is hopefully underway now to ensure that these fundamental research paths are realized and that translation to clinical applications is quickly and efficiently achieved. Current well-funded and focused translational research sponsorship efforts from federal agencies such as the National Institutes of Health, DOD, and AFIRM and state-based funding will potentially help scientist achieve functional repair of damaged tissues within 10 years and possibly full organ regeneration within 20 years. There is a continuous need for a more active role of the FDA in recognizing the challenges of these new medical technologies because well-defined guidelines, transparent support outreach, and education of researchers regarding the regulation process are required. In addition, more effective evaluation, support, and advisory roles are required for complex combinatorial products. This commitment to the future is encouraging, and the FDA remains actively involved in multiple innovative RM developmental paths.

Other countries have already embarked upon national initiatives of their own with hopes of making RM a reality for themselves. Several members of the European Union, including Great Britain, Germany, and Sweden, as well as Japan, China, India, and Australia have all begun making strong national commitments with hopes of achieving their own advances in RM technology.

Also of importance is the consolidation of synergistic efforts by representations from nonprofit, for-profit communities, patient advocacy groups, and government agencies for reimbursement and other outreach efforts to general public. US forums such as the Genetic Policy Institute and the Alliance for Regenerative Medicine (http://www.alliancerm.org) specifically represent the interests of RM companies, institutions, patients, policymakers, and researchers. The Regenerative Medicine Promotion Act of 2011 (HR 1862) was introduced in the House of Representatives on May 12, 2011, by Reps. DeGette (D-CO) and Bilbray (R-CA) with provisions including creation of a multiagency Regenerative Medicine Coordinating Council within the Department of Health & Human Services, establishing grant programs to accelerate the availability of life-saving RM therapies and research tools, funding of critical regulatory research at the FDA, and a detailed assessment of federal activities in RM as well as progress compared with national programs in other countries.

Today the RM industry is exclusively focused on translating science into commercial products, thus integrating the science into the health care system with effective production of automated support and servicing tools. Although there are many challenges, there is a strong base of public support for these modern RM opportunities to create curative therapeutics for a brighter future in disease management [99–102].

# Conventional and Novel Container Closure and Delivery Systems

JOSEPH WONG and MAHESH V. CHAUBAL

## 20.1 INTRODUCTION

### 20.1.1 Biologics: Market Growth for Biologics Delivery Technologies

Recent years have seen continued growth in the area of biologics with a majority of pharmaceutical companies developing pipeline in next-generation biologic products. The majority of biologics are administered via injectable routes of administration and often require frequent injections. Hence, delivery devices that can reduce discomfort associated with injectable delivery (both to the caregiver and the patient) are of interest as part of the lifecycle management of biologic products.

Growth in the area of biologics is expected to be fueled further with the anticipated advent of biosimilar products. In February 2012, the draft guidances on scientific and quality considerations in demonstrating biosimilarity to a reference product were provided jointly by Center for Biologics Evaluation and Research (CBER) and Center for Drug Evaluation and Research (CDER) [1,2]. The Food and Drug Administration's (FDA's) totality-of-the-evidence approach proceeds in a stepwise fashion by first demonstrating that the biological product is highly similar to the reference product analytically. Animal studies, including toxicity evaluation, are next followed by clinical evaluations on pharmacokinetics (PK), pharmacodynamics (PD), and immunogenicity. The first licensed interchangeable biological product will be granted a period of exclusivity. Under "Biosimilarity and Interchangeability," biosimilar products may have a different delivery device or container (e.g., prefilled syringe) compared with the reference product (e.g., vial) as long as compatibility is demonstrated [3].

From the perspective of both the innovator companies as well as biosimilars, differentiation of the product using novel delivery devices is critical. Furthermore,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

success of such products depends on an in-depth understanding of the interactions between the drug and the device. This chapter attempts to discuss some key features of delivery devices for biologics (both conventional and novel) that are important for consideration in product development.

### 20.1.2 Biological Product Attributes

The acceptability, in terms of safety, effectiveness, and quality, of a biologic product, is inseparably linked to its chemical nature, dosage and frequency, route of administration, formulation and dosage form, manufacturing process, and container and administration set or device. Safety or immunogenicity [4], in particular for biologics, is the primary concern. Protein aggregation caused by various factors (including undesirable interactions with device components) could elicit undesirable immunologic responses. Appropriate formulation design can help to improve on stability and preventing degradation, denaturation, and aggregation.

Because of the importance of the device, especially for biologic products, proteins or vaccine products in devices are treated as combination products.

### 20.1.3 Combination Products

Given that a majority of biologics are administered parenterally, the use of devices to improve on the ease of injection, and therefore lowering the labor burden for clinicians and increasing patient compliance in self-administration, has received significant attention. Products incorporating a drug formulated in an advanced device are now being considered as combination products. Prefilled syringes and insulin injector pens are examples of combination products. Biological products in solution formulation are frequently packaged as prefilled syringes [5].

Per the FDA's Office of Combination Products (OCP), which was established on December 24, 2002 [6], the definition of combination products includes (1) a drug and a device; (2) a biological product and a device; (3) a drug and a biological product; or (4) a drug, a device, and a biological product. The examples of FDA-approved combination products are available on the FDA's website [7]. Some examples are tositumomab and iodine $^{131}$I tositumomab (tositumomab covalently linked $^{131}$I) and the drug-eluting stent for clogged heart arteries (zotarolimus).

Drug-compatible containers are required to provide barrier properties to prevent degradation of the biologic as well as functional properties to maintain its utility over shelf life. The container should provide protection from light (if necessary), gas transmission (e.g., water, oxygen), and microbial contamination. The interaction of the biologics with leachables must not trigger safety concerns, and the marketing pack, a combination of primary (drug contact) and secondary (e.g., overpouch) packaging, must provide the performance as designed [8]. The FDA has recognized the greater potential for adverse effects associated with identity, strength, quality, purity, or potency to occur during storage or shipping for protein products. From a functional perspective, the device should provide reproducible dose delivery over its entire duration of use.

### 20.1.4 Guidance for Industry

The OCP strongly encourages the developer of a combination product to conduct early dialogue with the agency to resolve issues on preclinical and clinical testing [9] such as pharmacokinetic or dose range studies, for example, or to avoid duplicate studies. Guidance on early development considerations for innovative combination products is available [10]. Either with a new chemical entity or existing drug or biologic, the safety and efficacy of a combination product in terms of new use, indication, dosing, target population, route of administration, and so on need to be addressed in clinical investigation in addition to drug or biologic device compatibility and manufacturing.

The OCP does not regulate products. Rather, it designates a FDA Center (CDER, CBER, or Center for Devices and Radiological Health [CDRH]) for regulation for a combination product based on the product's primary mode of action (PMOA) [11]. The PMOA is defined as the most important therapeutic action of a combination product. For example, the drug is determined to be secondary to the stent in a drug-eluting stent, and the application is therefore assigned to CDRH for evaluation. For a prefilled syringe, the drug (or biological product) component has the primary role in therapy, and the syringe serves only to deliver the drug. Therefore, CDER (or CBER) reviews the application [12]. In some cases, CDER may request consultation from CDER. However, manufacturer of a combination product may request for designation because each center requires different current good manufacturing process program or adverse event reporting, for example.

## 20.2 GENERAL DEVELOPMENT APPROACH OF A COMBINATION PRODUCT (DRUG OR BIOLOGIC WITH DEVICE)

As mentioned earlier, biologics are typically administered as injections. Limited exceptions include proteins [13] such as DNase (Pulmozyme) delivered via nebulization for the treatment of cystic fibrosis and Exubera, an inhaled insulin, for type II diabetes, although the latter product was subsequently withdrawn from the market [14].

The nasal route has also attracted attention because of its potential for delivery to the central nervous system as well as for being an effective route for vaccination and for systemic delivery; the nasal route provides a large surface area for drug absorption ($\sim$160 $cm^2$). Examples of biologics approved for nasal delivery include FluMist influenza vaccine and low-molecular-weight peptides (e.g., Syntocinon, oxytocin [MW 1.0 kDa] for induction of labor; Miacalcin, salmon calcitonin [MW 3.4 kDa] for treatment of Paget's disease) [15].

For achieving sustained release after intramuscular injection, a peptide can be formulated in microspheres composed of polylactic glycolic acid (PLGA) (e.g., Lupron Depot [leuprorelin] and Zoladex [goserelin]) [16]. For each of these alternate routes of delivery, the use of an appropriate device becomes critical for effective delivery. For example, a nasal spray device is required for the effective administration of the FluMist vaccine. Similarly, a specialized injection device (SafeSystem

Syringe) was developed for the injection of the PLGA implant under the skin for Zoladex. Exubera involved an advanced delivery disperser that aerosolized dried insulin particles efficiently to deposit insulin to the appropriate region of the lungs. As suggested from these examples, each device has its own attributes that are specific to the route of administration or even to the specific molecule. Although each device has its route-specific functionality, we will attempt to discuss some of the attributes that could be generically applied to devices that are used for delivery of biologics or protein products.

The FDA has provided an overview of medical devices and regulatory pathways:

> Combination products raise regulatory challenges because they involve components that were normally regulated under different types of authorities and often by different FDA Centers. Differences in regulatory pathways for each component can affect the regulatory processes for all aspects of product development and management, including preclinical testing, clinical investigation, marketing applications, manufacturing and quality control, adverse event reporting, promotion and advertising, and post-approval modifications [17].

In the case of a device, a draft guidance was published for pen, jet, and related injectors for use with drug and biological products [18]. Typically, the device itself will go through premarket notification submission (510K) or premarket approval. In addition to the disclosure of the device design to perform accurate and safe delivery of single or repeated doses, human factor design consideration is also required. Simplicity is the key to accommodate the variability in the end-user population (e.g., elderly adults with arthritis) and environment (e.g., storage, use in high attitude). A device designed to incorporate human cognitive and ergonomic considerations should improve on patient compliance. Interestingly, the least burdensome provisions of the FDA Modernization Act apply to all devices and only the device components of combination products [19].

For the drug or biologic component of combination product that includes a device, a New Drug Application (NDA) or a Biological Licensing Application (BLA) is usually the route for marketing application. The demonstration of drug or biologic compatibility with the device during sterilization, storage, and use (e.g., potential biologic aggregation under pressurized delivery) is required. For prefilled syringe, the drug or biologic formulation or concentration can also impact on syringeable (e.g., viscosity) and extract chemicals from the device therefore affecting performance [20].

### 20.2.1 Approved Biologics in Conventional Delivery Packaging

Protein products are usually packaged as lyophilized cake for improvement of stability or dissolution if the drug formulation is stable in glass vials. Table 20.1 shows the currently US-approved protein products that are packaged in ready-to-use prefilled syringes or pens or in flexible containers (e.g., bag or blow-fill-seal [BFS] plastic ampoule) for room temperature, refrigerated, or frozen storage. Some packaging involves the requirement of using a filter needle in the preparation process, such as ranibizumab injection for treatment of patient with neovascular

**TABLE 20.1 Approved Biologics in Ready-to-Use Packaging Systems***

| Drug | Formulation and pH | Packaging | Administration Route |
|---|---|---|---|
| Adalimumab | Contains 40 mg adalimumab, 4.93 mg sodium chloride, 0.69 mg monobasic sodium phosphate dihydrate, 1.22 mg dibasic sodium phosphate dihydrate, 0.24 mg sodium citrate, 1.04 mg citric acid monohydrate, 9.6 mg mannitol, 0.8 mg polysorbate 80; and water for injection, USP at a pH of 5.2 | Prefilled syringe | SC |
| Albumin | For example, the 25% product contains 25 g of albumin (human) in 100 ml with no preservative and stabilized with *N*-acetyltryptophan and sodium caprylate at physiological pH; the sodium content is 145 ± 15 mEq/l | Multilayered plastic container (polyethylene solution contact layer) | IV |
| $\alpha_1$-Proteinase inhibitor ($\alpha_1$-PI) | The solution contains 2% active $\alpha_1$-PI in a phosphate-buffered saline solution | Each carton of GLASSIA contains a single-use vial containing 1 g of functional $\alpha$1-PI in 50 ml of solution and a sterile filter needle | IV |
| Anakinra | Each 1-ml syringe contains 0.67 ml (100 mg) of anakinra in a solution (pH 6.5) containing sodium citrate (1.29 mg), sodium chloride (5.48 mg), disodium EDTA (0.12 mg), and polysorbate 80 (0.70 mg) in water for injection, USP | Prefilled syringe | SC |
| Calcitonin | Each 3.7-ml unit contains calcitonin–salmon 2200 IU/ml, sodium chloride, citric acid, phenylethyl alcohol, benzyl alcohol, polysorbate 80, HCl/NaOH and purified water, USP | Glass bottle | Nasal spray |
| Catumaxomab | One 0.1-ml prefilled syringe contains 10 μg of catumaxomab in addition to sodium citrate, citric acid monohydrate, polysorbate 80, and water for injection | Prefilled syringe | IV |
| Certolizumab pegol [21] | Each 1-ml single-use prefilled syringe contains certolizumab pegol (200 mg), sodium acetate (1.36 mg), sodium chloride (7.31 mg), and water for injection, USP at a pH of ≈4.7 | Plastic prefilled syringe | SC |

(*continued*)

**TABLE 20.1** (*Continued*)

| Drug | Formulation and pH | Packaging | Administration Route |
|---|---|---|---|
| Choriogonadotropin-alfa | Each 0.5 ml prefilled syringe contains 257.5 μg of choriogonadotropin- alfa, 28.1 mg mannitol, 505 μg 85% O-phosphoric acid, 103 μg L-methionine, 51.5 μg Poloxamer 188 and water for injection at pH 6.5 to 7.5 | Prefilled syringe | SC |
| Darbepoetin-alfa | Each syringe contains 10 to 500 μg darbepoetin-alfa.; the excipients per milliliter are polysorbate 80 (0.05 mg), sodium chloride (8.18 mg), sodium phosphate dibasic anhydrous (0.66 mg), and sodium phosphate monobasic monohydrate (2.12 mg) in water for injection, USP (pH 6.2 ± 0.2) | Prefilled syringe and SureClick prefilled pen | IV, SC |
| Denileukin diftitox | Each 2-ml vial contains 300 μg of denileukin diftitox, citric acid (20 mM), EDTA (0.05 mM), and polysorbate 20 (<1%) in water for injection, USP at a pH of 6.9 to 7.2 | Denileukin Diftitox is supplied as a frozen solution in a single-use vial; store frozen at or below −10°C | IV |
| Denosumab | Each 1-ml single-use prefilled syringe contains 60 mg denosumab (60 mg/ml solution), 4.7% sorbitol, 17 mM acetate, 0.01% polysorbate 20, water for injection, USP, and sodium hydroxide to a pH of 5.2 | Prefilled syringe | SC |
| Dornase-alfa | The 2.5-ml solution in a single-use BFS ampoule contains 1.0 mg/ml dornase-alfa, 0.15 mg/ml calcium chloride dihydrate, and 8.77 mg/ml sodium chloride at a pH of 6.3 | BFS plastic ampoule [22] for nebulization | Inhale |
| Epoetin-α | Contains 100 to 40,000 units of epoetin-α in different syringe sizes and glycine (5 mg/ml), polysorbate 80 (0.3 mg/ml), sodium chloride at 1.7 to 5.8 mg, sodium phosphate–monobasic dihydrate at 0.35 to1.16 mg, sodium phosphate–dibasic dihydrate at 0.67 to 2.22 mg, sodium citrate at less than 5 mmol, and water for injection; the prefilled syringes are fitted with the PROTECS needle guard device to help prevent needle stick injuries after use | Prefilled syringe with PROTECS needle guard device | IV |
| Etanercept | Contains a 50-mg/ml solution of etanercept with 1% sucrose, 100 mM sodium chloride, 25 mM L-arginine hydrochloride, and 25 mM sodium phosphate at a pH of 6.3 ± 0.2 | Prefilled syringe and SureClick autoinjector | SC |

**TABLE 20.1** (*Continued*)

| Drug | Formulation and pH | Packaging | Administration Route |
|---|---|---|---|
| Filgrastim | Each syringe container either 300 or 480 μg filgrastim; the 480-μg/0.8 ml vial, for example, contains 480 μg filgrastim, 0.472 mg acetate, 40.0 mg sorbitol, 0.032 mg polysorbate 80, 0.028 mg sodium in water for injection, USP at a pH of 4.0 | Prefilled syringe | IV, SC |
| Follitropin-alfa | Contains 30, 41, or 75 μg follitropin-alfa, 60 mg/ml sucrose, 3.0 mg/ml m-cresol, 1.1 mg/ml disodium hydrogen phosphate dihydrate, 0.45 mg/ml sodium dihydrogen phosphate monohydrate, 0.1 mg/ml methionine, 0.1 mg/ml poloxamer 188 at a pH of 6.7 to 7.3 | Prefilled pen | SC |
| Golimumab [23] | Each 0.5-ml prefilled syringe contains 50 mg of the golimumab antibody, 0.44 mg of L-histidine and L-histidine monohydrochloride monohydrate, 20.5 mg of sorbitol, 0.08 mg of polysorbate 80, and water for injection at a pH of ≈5.5 | Prefilled glass syringe | SC |
| Goserelin | Goserelin acetate implant (1.5-mm diameter cylinder) is supplied as a sterile and totally biodegradable D,L-lactic and glycolic acids copolymer (12.82–14.76 mg/dose) impregnated with goserelin acetate equivalent to 10.8 mg of goserelin preloaded in a SafeSystem syringe; the aluminum foil laminate pouch is light and moisture proof, and the unit is stored at room temperature | Prefilled syringe to inject the implant | SC |
| Hematopoietic progenitor cord blood cells | Each unit contains a minimum of $5.0 \times 10^8$ total nucleated cells with a minimum of $1.25 \times 10^6$ viable $CD34^+$ cells, suspended in 10% DMSO and 1% dextran 40 at the time of cryopreservation | Plastic bag stored at or below −150°C | IV |
| Human insulin and combinations or analogs | Insulin example: Contains insulin lispro 100 units, 16 mg glycerin, 1.88 mg dibasic sodium phosphate, 3.15 mg metacresol, zinc oxide content adjusted to provide 0.0197 mg zinc ion, trace amounts of phenol, and water for injection at a pH of 7.0 to 7.8 | Prefilled pen | IV, SC |

(*continued*)

**TABLE 20.1** (*Continued*)

| Drug | Formulation and pH | Packaging | Administration Route |
|---|---|---|---|
| Icatibant [24] | Each 3-ml prefilled syringe contains equivalent to a 30-mg icatibant, sodium chloride, glacial acetic acid at a pH of ≈5.5 | Prefilled syringe | SC |
| Influenza vaccine (seasonal) | Each 0.5-ml suspension in prefilled syringe contains 45 μg hemagglutinin (three strains), octoxynol-10 (TRITON X-100) ≤0.085 mg, α-tocopherol hydrogen succinate ≤0.1 mg, and polysorbate 80 (Tween 80) ≤0.415 mg; 0.2 ml prefilled syringe for intranasal spray | Prefilled syringe | IM, intranasal spray |
| Interferon α-2a | Each 0.5-ml syringe contains 11.1, 22.2, 33.3 μg of interferon α-2a, recombinant; 3.605 mg sodium chloride; 0.1 mg polysorbate 80; 5 mg benzyl alcohol; and 0.385 mg ammonium acetate | Prefilled syringe | SC |
| Interferon α-2b | The multidose pens provide 3, 5, or 10 million IU per 0.2 ml; each ml contains 7.5 mg sodium chloride, 1.8 mg sodium phosphate dibasic, 1.3 mg sodium phosphate monobasic, 0.1 mg edetate disodium, 0.1 mg polysorbate 80, and 1.5 mg *m*-cresol | Multidose prefilled pen | SC |
| Interferon β-1a [25] | Each 0.5-ml (30-mcg dose) syringe contains 30 μg of interferon β-1a; 0.79 mg sodium acetate trihydrate, USP; 0.25 mg glacial acetic acid, USP; 15.8 mg arginine hydrochloride, USP; and 0.025 mg polysorbate 20 in water for injection, USP at a pH of ≈4.8. Each 0.5-ml (0.5-cc) syringe contains either 22 μg or 44 μg of interferon β-1a, 2 or 4 mg albumin (human) USP, 27.3 mg mannitol USP, 0.4 mg sodium acetate, water for injection USP; also available in other prefilled syringes with slightly different formulations (pH of 3.5–4.5) | Prefilled syringe, prefilled autoinjector (approved February 2012), lyophilized vial for reconstitution | IM, SC |
| Interferon β-1b | Lyophilized vial comes with its diluent in a prefilled syringe | Prefilled syringe | IM, SC |
| Leuprolide acetate for depot suspension | The prefilled dual-chamber syringe contains sterile lyophilized microspheres of leuprolide acetate incorporated in a biodegradable lactic acid polymer; for example, the 3-month 22.5-mg dose is administered as a single IM injection | Prefilled dual-chamber syringe | IM |

**TABLE 20.1** (*Continued*)

| Drug | Formulation and pH | Packaging | Administration Route |
|---|---|---|---|
| Liraglutide | Each 3-ml prefilled pen contains liraglutide 18 mg, disodium phosphate dihydrate 1.42 mg; propylene glycol 14 mg, phenol 5.5 mg; and water for injection | Prefilled pen | SC |
| Methoxy PEG–epoetin-β [26] | Single-use vials 50 to 1000 μg/ml; prefilled syringes containing 50 to 250 μg and 400 to 800 μg methoxy PEG–epoetin-β in 0.3 and 0.6 ml, respectively, are formulated in sodium phosphate, sodium sulfate, mannitol, methionine, and poloxamer 188 at a pH of 6.2 ± 0.2 | Prefilled syringe | IV, SC |
| Peginterferon-α-2a | Each 0.5-ml prefilled syringe contains pegylated interferon-α-2a (180 μg), NaCl (4.0 mg), polysorbate 80 (0.025 mg), benzyl alcohol (5.0 mg), sodium acetate trihydrate (1.03085 mg), acetic acid (0.0231 mg) at a pH of 6.0 ± 0.5 | Prefilled syringe | SC |
| Peginterferon-α-2b | A dual-chamber glass cartridge containing lyophilized peginterferon alfa-2b in one chamber and a second chamber containing sterile water for injection USP to a volume of 0.5 ml<br>The lyophilized powder contains 67.5, 108, 162, or 202.5 μg of peginterferon alfa-2b; 1.013 mg dibasic sodium phosphate anhydrous; 1.013 mg monobasic sodium phosphate dihydrate; 54 mg sucrose; and 0.0675 mg polysorbate 80 | Dual-chamber glass cartridge | SC |
| Sipuleucel-T | 250 ml suspension containing a minimum of 50 million autologous $CD54^{+}$ cells activated with PAP-GM-CSF in lactated Ringer's injection, USP | Infusion bag (suspension) | IV |
| Somatropin | Intra-Mix example: a two-chamber cartridge with the front chamber contains powder mixture of recombinant somatropin 5.8 mg glycine 2.2 mg, mannitol 1.8 mg, sodium dihydrogen phosphate anhydrous 0.32 mg, and disodium phosphate anhydrous 0.31 mg; the rear chamber contains 0.3% | Intra-Mix: the powder and the diluent are mixed when the front and rear chambers are screwed together | SC |

| | m-Cresol and mannitol 45 mg in 1.14 ml water for injection; the reconstituted pH is ≈6.7<br>MiniQuick example: A single-use syringe device containing a two-chamber cartridge; the front chamber contains recombinant somatropin 0.22 to 2.2 mg, glycine 0.23 mg, and mannitol 1.14 mg, sodium dihydrogen phosphate 0.05 mg, and disodium phosphate anhydrous 0.027 mg and the rear chamber contains mannitol 12.6 mg in water for injection 0.275 ml; the reconstituted pH is ≈6.7<br>Nu Spin 10 contains 10 mg somatropin, 17.4 mg sodium chloride, 5 mg phenol, 4 mg polysorbate 20, and 10 mM sodium citrate at a pH of ≈6.0 | | |
| Streptococcal 13-valent vaccine | Each 0.5 ml contains ≈2.2 μg of each of the *Streptococcus pneumoniae* serotypes saccharides, 4.4 μg of 6B saccharides, 34 μg $CRM_{197}$ carrier protein, 100 μg polysorbate 80, 295 μg succinate buffer, and 125 μg aluminum as aluminum phosphate adjuvant | Prefilled syringe (suspension) | IM |
| Teriparatide | Each ml contains 250 μg teriparatide, 0.41 mg glacial acetic acid, 0.1 mg sodium acetate (anhydrous), 45.4 mg mannitol, 3 mg metacresol, and water for injection at a pH of 4 | Prefilled delivery device | SC |
| Ustekinumab | Each 45-mg ustekinumab prefilled syringe, for example, contains L-histidine and L-histidine monohydrochloride monohydrate (0.5 mg), polysorbate 80 (0.02 mg), and sucrose (38 mg) to fill to a final volume of 0.5 ml at a pH of 5.7 to 6 | Prefilled syringe | SC |

*Some of these listed drugs were not approved via OCP, as OCP was established on December 24, 2002. Insulin, for example, delivered via a pen is regulated by CDER.
BFS: blow-fill-seal; DMSO: dimethyl sulfoxide; EDTA: ethylenediaminetetraacetic acid; GM-CSF: granulocyte-macrophage colony-stimulating factor; IM: intramuscular; IV: intravenous; PAP: prostatic acid phosphatase; PEG: polyethylene glycol; SC: subcutaneous; USP: United States Pharmacopeia.

(wet) age-related macular degeneration. Others are designed for inhalation, for example, via nebulization for Pulmozyme. As inhaled insulin, Exubera, which was approved via OCP, is no longer available in the US market; it is not listed in this table. However, the packaging materials suitable for packaging powder for inhalation are discussed later.

### 20.2.2 Current Protein Drug Delivery Systems

The short half-lives typically associated with proteins and peptides often lead to the need for frequent injections. Hence, delivery devices that can ease the injection process, reduce the pain of injection, and improve on patient compliance are desirable. The current drug delivery systems designed for peptides and proteins are directed more to patient and clinician convenience and compliance (self-administration) presented in the form of prefilled syringes or pens. The ready-to-use large-volume parenteral in the form of premix in a flexible container is also available for intravenous (IV) administration in clinical settings.

## 20.3 CONTAINERS AND PRODUCT QUALITY

Product containers act as a barrier for light, oxygen, and moisture for protein products, wherein the protein may be formulated as solution, dispersion, or solid (including lyophilized cake). The moisture barrier is of particular importance for lyophilized products. However, escape of moisture from solution or dispersion through the container can affect the concentration and therefore dosing of these potent pharmaceuticals. A common remedy includes the use of an overpouch for containers that do not provide sufficient water vapor barrier properties. A foil overpouch may act as a barrier for light, oxygen, and moisture, as in the case of Zoladex (goserelin acetate, synthetic analogue of luteinizing hormone–releasing hormone, an implant).

### 20.3.1 Glass Containers

United States Pharmacopeia (USP) describes three types of glass, Types I, II and III, all of which are suitable for parenterals as long as compatibility is demonstrated. Type I glass is the most commonly used material for parenteral products. Although believed to be inert, Type I glass can participate in several interactions with the drug. These interactions could be with leachables from the glass surface (e.g., di- and trivalent cations released at neutral to high pH) or directly with the drug through electrostatic forces that can cause hydrophilic proteins to bind to the hydrophilic glass surfaces [27,28]. Glass can be purposely treated to turn the surface hydrophobic, such as Schott Type I Plus coated with silicon dioxide ($SiO_2$).

In one study, the interaction with containers, including untreated glass, siliconed glass, sulfur-treated glass, and plastic vials (polyester, polypropylene, and nylon) was found not to be correlated with molecular weight or isoelectric point for six proteins

studied [29]. Among the surface materials studied, glass appeared to bind the least amount of protein. Furthermore, adsorption to container surfaces appeared not to be an issue for proteins above 5 to 20 μg/ml. This finding was generally in agreement with a separate study [30], which indicated that whereas a 2.5-ppm immunoglobulin G (IgG) solution stored in a 50-ml ethylene–vinyl acetate (EVA) bag with 200 $cm^2$ surface area lost 32% (or 0.2 $\mu g/cm^2$ adsorption), a 50-ppm solution lost only 4% (or 0.5 $\mu g/cm^2$ adsorption).

***20.3.1.1 Protein Adsorption to Siliconed Glass Syringe or Vial Surface*** As mentioned in the previous section, hydrophobic silicone coating is sometimes used to reduce the adsorption of low-concentration potent biologics to the hydrophilic glass surface [31]. Silicone oil is also ubiquitously applied to various drug solution contact surfaces in devices such as on rubber stoppers (to prevent the sticking of the stoppers in bulk sorting and capping of vials during manufacturing of the parenteral products after solution aseptic filling), syringe barrels to allow smooth glide, and even to needle surfaces.

However, silicone oil on a device surface may be detrimental to the biologic because it has been identified as a possible contributing factor for protein aggregation. This silicone oil–mediated mechanism appears to be supported by the results of a separate study that investigated the effects of agitation, temperature, pH, and ionic strength in the induction of protein aggregation in the presence of silicone oil. A monolayer of protein was reported to absorb to silicone oil. The pH at a value close to the iso-electric point (PI) of the protein, and the increasing in ionic strength caused protein destabilization. It was also observed in this study that isothermal incubation in the presence of silicone oil did not affect protein aggregation except after shaking [32]. Thus, the combination of agitation and silicone oil is concluded to cause a synergistic stimulation of protein aggregation. However, it may be oversimplified to associate agitation and the presence of a hydrophobic surface with protein aggregation. For example, insulin dimerization occurs through interaction of the two hydrophobic regions of an insulin monomer. Destabilization of insulin is initiated with the adsorption of monomer to a hydrophobic surface. It is the dimerization at higher overall insulin concentration that reduces the concentration of hydrophobic insulin monomer and thereby reduces its destabilization [33]. Denaturation at the hydrophobic surface is unlikely for the hydrophilic hexamer, which is conformationally stable. Again, insulin hexamer is formed at a high concentration, such as 100 unit/ml in commercial products, and especially in the presence of zinc and m-cresol [34]. At a low infusion rate of 0.25 ml/min and at a low concentration of 0.1 unit/ml, the loss of regular human insulin to adsorption to some IV infusion bag and tubing was substantial [35]. Thus, the polymeric state of a protein in a formulation, in some cases, may affect adsorption to silicone-coated surfaces. Removal of silicone oil is a good solution for reducing protein aggregation. However, silicone oil is required for the functionality of the container, syringe, or device. The removal of silicone can therefore pose a different set of problems.

Application of a protein formulation strategy may resolve or reduce the container adsorption issue. If protein adsorption to glass occurs via electrostatic interaction, the

addition of a surfactant such as polysorbate 20 could reduce protein loss for susceptible proteins [36]. If the container surface is coated with silicone oil, polysorbate 20 may also completely inhibit silicone oil induced protein loss via agitation [32,36].

***20.3.1.2 Glass Container Delamination*** Glass is a highly viscous, supercooled liquid that for practical purposes behaves like an amorphous solid. When exposed to harsh processing conditions followed by sustained exposure to corrosive formulations, glass can form flakes at the surface, a phenomenon termed *delamination*.

*Glass Delamination Mechanism* In recent years, there has been a rise in product recalls because of glass delamination. Table 20.2 provides a list of biologics that have been subject to recent recalls. Although the issue appears to be multicausal, several proposed mechanisms of glass delamination and the methods for detection have been published [37]. In general, a number of factors are involved, including the pH of the product formulation, glass composition, method of glass container production, surface area treatment, and so on. The chemical compositions of some type I glass compositions are available as technical data from manufacturers and can be downloaded from the Internet [38]. Either leaching and ion exchange or glass dissolution was involved in the

**TABLE 20.2 Formulations of Recently Recalls of Biologics Caused by Glass Delamination**

| Drug | Manufacturer | Sterilization | pH | Composition |
|---|---|---|---|---|
| Epogen | Amgen | Aseptic | 6.9 | Epogen is formulated as a sterile, colorless liquid in an isotonic sodium chloride–sodium citrate buffered solution or a sodium chloride–sodium phosphate buffered solution for IV or SC administration<br>**Single-dose, preservative-free vial:** each 1 ml of solution contains 2000, 3000, 4000 or 10,000 units of epoetin-α; 2.5 mg albumin (human); 5.8 mg sodium citrate; 5.8 mg sodium chloride; and 0.06 mg citric acid in water for injection, USP (pH 6.9 ± 0.3); this formulation contains no preservatives<br>**Single-dose, preservative-free vial:** 1 ml (40,000 units/ml); each 1 ml of solution contains 40,000 units of epoetin-α, 2.5 mg albumin (human), 1.2 mg sodium phosphate monobasic monohydrate, 1.8 mg sodium phosphate dibasic anhydrate, 0.7 mg sodium citrate, 5.8 mg sodium chloride, and 6.8 mcg citric acid in water for injection, USP (pH 6.9 ± 0.3); this formulation contains no preservatives |

| Drug | Manufacturer | Sterilization | pH | Composition |
|---|---|---|---|---|
| | | | | **Multidose, preserved vial:** 2 ml (20,000 units, 10,000 units/ml); each 1 ml of solution contains 10,000 units of epoetin-α, 2.5 mg albumin (human), 1.3 mg sodium citrate, 8.2 mg sodium chloride, 0.11 mg citric acid, and 1% benzyl alcohol as preservative in water for injection, USP (pH 6.1 ± 0.3) |
| | | | | **Multidose, preserved vial:** 1 ml (20,000 units/ml); each 1 ml of solution contains 20,000 units of epoetin-α, 2.5 mg albumin (human), 1.3 mg sodium citrate, 8.2 mg sodium chloride, 0.11 mg citric acid, and 1% benzyl alcohol as preservative in water for injection, USP (pH 6.1 ± 0.3) |
| Hylenex | Halozyme | Aseptic | 7.4 | Hylenex recombinant (hyaluronidase human injection) is supplied as a sterile, clear, colorless, nonpreserved, ready-for-use solution; each milliliter contains 150 USP units of recombinant human hyaluronidase with 8.5 mg sodium chloride, 1.4 mg dibasic sodium phosphate, 1.0 mg albumin human, 0.9 mg edetate disodium, 0.3 mg calcium chloride, and sodium hydroxide added for pH adjustment; Hylenex recombinant has an approximate pH of 7.4. |

IV: intravenous; SC: subcutaneous; USP: United States Pharmacopeia.

first step in disruption of the glass matrix. In general, a leaching or ion-exchange process was the dominant process in an acidic solution. In an alkaline solution, the dominant process was glass dissolution. At a neutral pH, both leaching and ion exchange and glass dissolution occurred [39]. The recommended pH range for a solution formulation is between 4 and 8.

In the leaching and ion-exchange process, the sodium ions in the glass exchange with hydrogen ions in the solution, leading to an accumulation of hydrogen ions in the glass matrix. In basic solution, glass dissolution occurs; it also occurs with the release of sodium ions from the glass into the solution. The increase of ions on the glass surface decreases the hydrolytic resistance of glass, further driving ion leaching [40]. Another proposed mechanism involves the diffusion of molecular water into silicate matrix of glass that contains alkali oxides and then displaces sodium ions form glass into the solution. In the dissolution process, each $SiO_2$ molecule reacts with two molecules of water that has been diffused into the matrix to form silicic acid ($H_4SiO_4$). At a pH of 8, $H_4SiO_4$ reacts with hydroxyl ion to form soluble silicate ($H_3SiO_4^-$), thereby driving the equilibrium for further dissolution of $H_4SiO_4$ [41].

It is also observed that the first step in the glass delamination often occurs near the drug solution fill line. The precursor to glass delamination is pitting. As pitting increases, the borders of multiple pits overlap and cause pieces of glass to flake or delaminate [42]. Microscopic techniques are generally used in the detection of flakes from the delamination of glass surface [37,43].

*Effects of Product Formulation on Glass Delamination* In addition to pH as discussed earlier, the selection of buffer may also contribute to glass delamination. Anions and cations may exacerbate glass delamination. Citrate, for example, could form soluble complexes with silica in a neutral solution [44]. Parenteral solutions are usually formulated iso-osmotic or isotonic. An increase in ionic concentration could decrease the hydrolytic resistance of glass, which could further drive ion leaching from the glass surface [40]. The formulations of some recalled products are listed in Table 20.2.

*Glass Processing and Product Storage* Protein products in prefilled syringes and glass vials are produced via sterile filtration. However, syringes and glass vials still need to go through depyrogenation and sterilization steps before filling of the protein or peptide solutions can proceed. Depyrogenation does not appear to cause generation of glass flakes because unprocessed vials also showed erosion at in controlled studies [45].

In general, delamination increases with increasing storage temperature and time. Treatment of the glass surface could reduce glass delamination. The coating of $SiO_2$ turned the hydrophilic glass surface to hydrophobic and therefore offered some protection against delamination. Plastic prefilled syringes may also be used to avoid the issue of glass delamination.

### 20.3.2 Containers for Light-Sensitive Products

Type I glass is made of borosilicate, and the solution contact surface is hydrophilic for containers that have not been surface treated/coated. For providing ultraviolet and visible light protection, iron only in oxidized state ($Fe^{3+}$) and manganese are incorporated in the amber Type I glass. Type II is soda-lime glass that is suitably dealkalized. Both Type I and II glasses are suitable for packaging neutral and acidic solutions and need suitability evaluation for alkaline products. Type III glass is also soda-lime glass. It has been published that sulfur in the reduced state ($S^{2-}$) provides ultraviolet and visible light protection in amber Type III glass – amber Type III glass still contains relatively low amount of $Fe^{2+}$ and $Fe^{3+}$. Since $S^{2-}$ is not soluble in Type I glass, amber Type I glass may not be sterilized by gamma irradiation, as the $Fe^{3+}$ acts as an electron trap and causes darkening of the amber Type I glass [46]. Bacitracin for injection, a polypeptide antibiotic, is recommended to be stored at 2 to 8°C and protected from direct sunlight. However, bacitracin for injection is packaged in a clear glass vial and stored in a paper carton. This marketing pack should provide adequate light protection per ICH (Q1B) guidelines [47]. As an alternative, some laboratory chemical suppler, for example, indeed offers bacitracin in an amber vial. A recent commentary suggested changes to the guideline to include photostability of drugs under conditions of patient use [48]. As such, one approach of product life

cycle management can simply be repackaging current biologics in a carefully screened and compatible amber glass container.

In addition to vial products, a number of protein product prefilled syringes are required to be protected from light. Because of the need to inspect a parenteral solution before injection, amber glass is not an appropriate choice for prefilled syringe products. As an example, epoetin-α prefilled syringe has a storage temperature requirement of between 2 to 8°C with no freezing or shaking. The syringe also needs to be protected from exposure to light. Hence, the epoetin-α formulation is packaged in a clear syringe inside a paper carton.

### 20.3.3 Hydrophobic Surface Interaction: Flexible Containers

The USP states the requirements for plastic containers [49]. For flexible containers, coextrusion technologies allow the production of multilayer films with external and solution contact layers. Both of these layers will usually provide the structural strength of the container and the middle layer(s), if needed, can provide the gas and moisture barriers. Coextrusion is the extrusion of multiple layers of material using a single extrusion head or die. Containers made of multiple thin layers of films with different properties for structure and barrier functionalities are likely to provide superior functionality relative to a simple layer of thicker material. However, coextrusion of dissimilar material layers may result in poor adhesion. High-density polyethylene (PE), for example, has poor adhesion to ethylene vinyl alcohol. An extrudable adhesive such as polyurethane may be needed to bond the layers. The common polymers for the external and solution contact layers are polypropylene, PE, polystyrene, or their combinations. The common materials offering oxygen and moisture barriers are polyvinylidene chloride, ethylene vinyl alcohol, nylon, and metalized films [50]. In the case of ethylene vinyl alcohol, hydrolytic degradation by moisture occurs, and this material is therefore not as commonly used in containers for liquid or dispersion formulations.

The oxygen transmission rate (OTR) measured as milliliter per film thickness (mil) per 100 $in^2$ per day is usually measured at 73°F and at a relative humidity for the specified storage condition. For polyvinylidene chloride and ethylene vinyl alcohol, the OTR is below 0.1.

The water vapor transmission rate (WVTR), in some cases, is measured at 100°F and at 90% relative humidity, but test conditions for a final product may vary. For polyvinylidene chloride and ethylene vinyl alcohol, the WVTR values (g/mil/100 $in^2$/24 h) were 0.22 and 1.4, respectively [51]. Polychlorotrifluoroethylene has a WVTR of lower than 0.03 and is used in blister packaging for powder for inhalation.

In terms of adsorption to IV sets and containers, there are publications stating that insulin is adsorbed to glass and plastic materials such as polyvinyl chloride (PVC), PE, and other polyolefins [52]. Estimates of adsorption (loss) of insulin are in the 20 to 30% range. The adsorption extent was also reported to be inversely proportional to insulin concentration. The mechanism for insulin adsorption to surfaces has been published [27]. The surface of an insulin monomer is predominately hydrophobic amino acids. Dimerization involves the weak van der Waal's force and hydrogen bonding in the pleated sheet region [53]. At high concentration and especially in the

presence of zinc ion ($Zn^{2+}$), the monomers associate into hexamers that are hydrophilic.

For hydrophobic surfaces such as PVC [54], insulin monomer absorbs onto the PVC surface via hydrophobic interaction. Albumin, a high-molecular-weight protein that exhibits a high affinity for substrate, may be used to displace adsorbed insulin, which has a smaller molecular weight and is therefore faster in diffusion in the competitive adsorption process [27].

High-density polyethylene (HDPE), a common polymer used in plastic containers, also has a hydrophobic surface. The adsorption of albumin (HSA), for example, onto HDPE was found to be consistent with the formation of a close-packed monomolecular layer and independent of HSA concentration. HSA is bound to HDPE by dispersion forces; the adsorption was irreversible probably caused by HSA conformational changes. Adsorption stops after HSA occupies all the adsorption sites on the HDPE surface [55,56].

Just like HDPE, linear low-density polyethylene (LLDPE) used in certain flexible container is also known to be hydrophobic. The contact angle for LLDPE is about 100 degrees [57]. Contact angle is a measurement of hydrophobicity; contact angles above 90 degrees are defined as hydrophobic. In a separate study, a stable reading of contact angle for water on PE surface of about 100 degrees could be achieved in about 10 min [58].

For PVC, the published contact angle is 97.7 degrees [59]. LLDPE is therefore similar to hydrophobicity of PVC, if not slightly more, and should not be expected to be acceptable in insulin monomeric adsorption [52]. A short-term adsorption study of bovine insulin (2.5 μg/ml in phosphate buffer saline at a pH of 7.4) to PVC and LLDPE was published [30]. As expected, bovine insulin adsorption to LLDPE (0.10 $\mu g/cm^2$) was actually higher than that to PVC (0.07 $\mu g/cm^2$).

### 20.3.4 Protein Aggregation via Interaction with Tungsten in a Container or Device

Devices such as prefilled syringes have additional material considerations that should be evaluated. For example, tungsten leachables in a prefilled syringe is a known culprit for protein aggregation [60]. A tungsten pin is typically used during the syringe manufacturing process to produce the needle hole at the base of the syringe. This process leads to the deposition of vaporized tungsten species, such as tungsten oxide, and glass materials on the solution contact surface of the syringe barrel. The conclusion from the published paper indicated that the extent of the protein aggregation was dependent on

1. Tungsten concentration and specific tungsten species
2. Protein concentration and characteristics of a protein
3. pH of the buffered formulation

In general, the lower the pH and the higher the tungsten concentration, the more protein aggregation; a reaction between an α-helix protein and tungsten followed a

constant stoichiometry. Electrostatic interaction, rather than unfolding or hydrophobicity, between protein in native structure and tungsten molecules appears to be the mechanism for aggregation.

## 20.4 RECENTLY MARKETED AND EMERGING CONTAINER PLATFORMS

### 20.4.1 Nonsiliconed Plastic Syringe

The silicone oil–free, cyclic olefin polymer [61] prefillable syringe, for example, is marketed to be suitable for biologics. This prefillable syringe is claimed to reduce the extent of protein aggregation following agitation, shipment, and storage conditions [62]. The functionality (lubricity and seal integrity) of this syringe piston is maintained via lamination with a polymer film (e.g., fluorocarbon polymer) instead of silicone oil. This polymer film serves to lower protein adsorption and act as a barrier to leachables. The manufacturing of the syringe components does not include tungsten pins. The plastic syringe is also breakage resistant.

### 20.4.2 Flexible Plastic Containers

Given some of the challenges associated with glass containers, there has been an interest in evaluating the use of flexible plastic containers for ready-to-use biologic solution products. FLEXBUMIN (human albumin 25%) is the first FDA-approved product of a biologic solution in a flexible plastic container suitable for room temperature storage. Flexible containers offer various benefits for protein solutions, including eliminating delamination risks, resolving potential glass incompatibility issues, and improving ease of administration by reducing the steps in reconstitution.

## 20.5 BLOW-FILL-SEAL PLASTIC AMPOULE

Blow-fill-seal technology can be used in packaging particle-free, sterile fill injectable solutions. This BFS technology may also be used to package drug solutions for other routes of administration, such as eye drops, and even for packaging of food and cosmetic products. There have also been announcements that prefilled syringes, with or without pistons, could be manufactured using this cost-effective technology. The steps for washing, depyrogenation, and sterilization of the container by gamma irradiation are eliminated.

One example of a biologic in a plastic BFS ampoule is Dornase Alfa for nebulization. BFS, on one hand, has the advantage of molding, sterile filling, and sealing the biologic in a simplified manufacturing process. However, the extrusion of the container requires the heating of the polyolefin resin (e.g., polypropylene and PE) to up to 160°C. In addition to volatile solvent and leachable protein interactions, the relatively higher temperature experienced in manufacturing may also contribute to

protein instability or eliciting immune responses, especially for large, complex, or temperature-sensitive proteins [22].

## 20.6 NONPARENTERAL DELIVERY

Devices have been developed for multiple nonparenteral administration of biologics. Pulmonary delivery devices have been in common use and are considered out of scope for this chapter. However, readers are referred to an excellent review by Byron [63]. Delivery devices have also been used for transdermal and nasal delivery of biologics. Principally, all of the considerations in this chapter are applicable to such devices as well. For transdermal devices, an FDA guidance has been developed to evaluate the completeness of dose delivered (and residual drug in device).

## 20.7 DEVICE FUNCTIONALITY TESTING

The two major functions of any drug delivery device are to protect the drug from degradation and to deliver the right dose every time. The earlier sections discuss various aspects of compatibility between the drug and the device surface. Additional consideration should be provided for the compatibility of the drug during functional operation of the device. For example, gas-powered devices (for jet injectors) may lead to stress during drug administration, which may be detrimental to a protein drug. Functionality of the device to ensure consistent delivery over the entire shelf life is a key consideration.

Yet another consideration during device development is the human factor aspects. For example, prefilled syringes with larger than normal flanges can improve ease of use for patients with arthritis. The piston breakaway force and the glide force for a syringe are often evaluated as critical product attributes during aging studies wherein the forces have to stay within limits previously determined using human factor studies. For complex devices, detailed verification and validation studies are required to demonstrate that the device performs per its specifications over the entire shelf life of the product.

## 20.8 RECOMMENDATIONS

Any new drug delivery device needs to take into account the interactions between the drug and the container or device, as well as the functionality of the device. On the assumption that the route of administration for a drug or biologic in a device such as inhalation or injection is decided, the following steps are recommended for the choice of a container for a combination product:

1. *Characterization of the protein or peptide at the concentration and the associated formulation intended for use:* It is important to understand the protein state, as well as hydrophilicity or hydrophobicity at the intended

concentration and pH. All of these parameters lead to the understanding of formulation flow (viscosity), which may affect functionality of the device such as syringeability, for example.

2. *Evaluation of containers' key quality attributes:* The hydrophilicity or hydrophobicity of the surface of a container needs to be examined. Removal of silicone oil coating or use of a silicone oil–free container may be preferable under certain circumstances. If the delivery systems involve mechanical pumping, agitation in the presence of silicone oil may cause aggregation. The addition of a surfactant such as polysorbate 20 may be an option in formulating the drug if a metal component is present in the device. However, a high level of surfactants that may be used to stabilize a protein may extract components from the device, causing incompatibilities.
3. *Choosing different containers:* A short-term design of experiment is usually conducted to screen out potential containers in terms of performance, such as depth of the insertion or injector or orifice size, and compatibility. If container cost constitutes a relative low percentage of the cost of the combination product, the strategy is to first screen a silicone oil–free, cyclic olefin polymer prefillable syringe for an injectable just to avoid the potential issues with silicone oil, tungsten, and extractives. All in all, the drug–biologic compatibility assessments with the device during sterilization, storage, and use (e.g., potential biologic aggregation under pressurized delivery) are required.
4. *Human factor considerations:* Simplify the device design to accommodate human cognitive and ergonomic considerations for accurate and safe delivery of the dose to improve on patient compliance.

A careful strategy must be adopted to assess protein aggregation via interaction with the selected container, which may result in unwanted immunogenicity. The ultimate goal is to market a safe, effective, easy-to-use, and cost-effective combination product to provide mutual benefits to both patients and the developer.

# Controlled-Release Systems for Biologics

MAYURA OAK, RHISHIKESH MANDKE, BUDDHADEV LAYEK, GITANJALI SHARMA, and JAGDISH SINGH

## 21.1 INTRODUCTION

Recent progress in genetic engineering and pharmaceutical technology has resulted in identification and commercial availability of a number of new biologics with distinct therapeutic activities [1]. The "biologics," in practical term, encompass a variety of products such as recombinant proteins, vaccines, blood and blood components, allergenics, somatic cells, tissues, and gene therapy [2]. The market of recombinant DNA (rDNA)–derived protein and peptide therapeutics has seen a sustained growth and is expected to increase with a compound annual growth rate of more than 10% in 2013 [3]. Monoclonal antibodies (mAbs), another class of biologics, are considered as a second wave of innovation next to recombinant proteins [4]. The demand for mABs is also continuously increasing and should be estimated in billions of dollars per year. The demand for vaccines has also shown a continuous rise with a predicted annual growth of approximately 6.5% [5].

The major concerns about delivering biologics, especially peptides and proteins, are their unique physicochemical properties, delicate structures, and short biological half-lives. Understanding stability issues associated with biologics and their degradation mechanisms is essential for developing successful therapeutics. Most of these protein- and peptide-based pharmaceuticals are administered by frequent injections either in solution or suspension dosage forms. This approach is rather inconvenient for patients, often requires medical personnel or hospitalization, and is therefore expensive. Similar to proteins, mAbs have a delicate structure that makes them more susceptible to conformational changes during formulation of injection and storage. Typical delivery routes for mAbs are intravenous (IV) and subcutaneous (SC) and involve several doses, thus emphasizing the need for controlled-release formulations.

Gene therapy, another area of biologics, holds a great promise when the impaired gene is replaced with its correct copy for the normal functioning of affected cell. Although it has excellent therapeutic potential, the issues involving safety,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

therapeutic efficacy, duration of desired effect, and ability to deliver gene to the correct target cell make it difficult to gain clinical acceptance. In the case of vaccines, the need for multiple doses raises a patient compliance issue; therefore, development of a more efficient single administration delivery system is of prime importance. Thus, translating these biologics into convenient medicines requires parallel development of drug delivery technologies.

Controlled drug delivery can be helpful to address the drawbacks associated with traditional methods of administration of biologics. Recently, development of an effective controlled-release system to deliver biologics in a stable and biologically active form has drawn greater attention. Controlled delivery could allow a drug to be delivered at a controlled rate and maintained in a desired therapeutic window for days to months or even for years. The primary objective of controlling the drug delivery is to attain effective drug level for a longer duration, thus reducing the injection frequency and the possibility of accidently administering higher or lower doses.

The most widely used routes for sustained release systems are SC and intramuscular (IM) [6]. For most of the formulations of biologics, delivery via parenteral route shows strong growth prospects and therefore is of prime importance. The significant benefits of parenteral controlled-release systems over conventional delivery systems for peptides and proteins, including mAbs, are minimal side effects and toxicity caused by maintenance of a constant drug level, controlled-release rate and duration, reduced cost because of optimum use of the drug administered, the need for fewer injections, and increased patient compliance by reducing the frequency of dosing, leading to improved patient comfort. Using polymeric controlled-release systems for DNA delivery can potentially help to reduce the limitations of achieving safe and adequate therapeutic effect associated with gene therapy. Several natural and synthetic polymeric vectors have been used as controlled-release systems for DNA delivery.

In the case of conventional vaccines, the major cause of immunization failure is patient negligence toward booster doses of vaccines. Controlled vaccine delivery could be helpful in developing sustained and persistent immune responses because it allows incorporation of larger doses of antigen that can be released continuously for prolonged periods, eliminating the need of booster doses [7]. DNA vaccine is another type of vaccine delivery method in which gene encoding for protein antigen is administered into host cells, enabling antigen production to occur *in vivo* [8]. This continuous and sequential presentation of antigen to the immune system is effective in eliciting a prophylactically important immune response. However, in addition to the aforementioned advantages, development of controlled-release delivery systems for biologics still faces certain obstacles such as low drug loading; physical and chemical instability; and low biological activity caused by processing conditions, instability during storage, sterility issues, and a significant burst effect or dose dumping after being placed in the body [9,10].

### 21.1.1 Polymeric Controlled Delivery Systems

Many research groups have focused on the development of polymeric delivery systems for the delivery of biologics at a controlled rate as per the treatment need.

Various natural and synthetic polymers have been explored as delivery vehicles to achieve controlled release and at the same time preserve the stability of incorporated drugs during storage and release [11]. The polymeric delivery systems could be the matrix or reservoir type. A drug is dispersed or dissolved in the matrix-type delivery system, and its release depends on diffusion, polymer swelling, degradation and erosion; in case of a reservoir-type delivery system, a drug gets surrounded by polymer, forming a diffusion barrier. Therefore, the rate of release depends on the dissolution of drug into polymeric phase and diffusion through polymer walls [12]. The polymer-based delivery systems are broadly classified into particulate delivery systems, gels, suspensions, solutions, emulsions, implants, and drug-eluting stents. Polymers of a biodegradable nature are gaining importance because they undergo enzymatic or nonenzymatic degradation *in vivo* and produce biocompatible, non-toxic byproducts that are further metabolized or eliminated from the body [9]. Additionally, the delivery systems containing biodegradable polymers do not need surgical explantation.

Because of the uncertain purity and high cost of natural polymers, synthetic biodegradable polymers are increasingly used for controlled delivery of proteins and peptides. These include polyesters (lactide and glycolide polymers), poly(caprolactones), poly(phosphoesters), polyanhydrides, block copolymers, poly(amino acids), poly(urethanes), and so on [9,13]. Among these polymers, poly(lactic acid) (PLA), poly(lactic-*co*-glycolic acid) (PLGA), and their copolymers have been extensively used as controlled delivery vehicles because of their biodegradable and biocompatible nature.

## 21.2 CHOICE OF A SUITABLE DELIVERY SYSTEM

The choice of a delivery system depends on the clinical outcome of the therapeutics. The designing of a controlled delivery system involves concurrent consideration of various aspects of vehicles or polymers, drugs, release mechanisms, release duration, and administration routes [14]. These factors are interdependent and have a profound effect on advancement of the biologics from bench to clinic. Figure 21.1 summarizes the various factors which need to be considered while developing a controlled delivery system for any biotherapeutic agent [11].

### 21.2.1 Characteristics of Polymeric Delivery Systems

The following characteristics are desirable for polymeric delivery systems:

1. Polymers should degrade slowly over the period of time that corresponds with their function [13,15].
2. The delivery system should be easy to formulate and should have enough mechanical stability for desired release duration [9,15].
3. Polymer degradation products should be nontoxic, biocompatible, and easily absorbed or eliminated from the body [13,15].

**FIGURE 21.1** Factors to be considered during development of a controlled delivery system. IM: intramuscular; SC: subcutaneous.

4. The delivery system should not produce any immune reaction or inflammation after injection or implantation [15].
5. The delivery system should not alter the stability and therapeutic efficacy of the incorporated drug molecules.
6. Most importantly, the delivery system should release the incorporated molecule for the designated period at a controlled rate in a stable and biologically active form.
7. In the case of DNA, the delivery system should not release the contents until it reaches the target site, and it should be able deliver the gene of interest to the specific target cell.
8. The delivery system should be able to cross the cell membrane barrier and reach the nucleus and deliver the gene to the nucleus upon reaching; thus it should show a delayed-release profile.
9. The delivery system should have good DNA condensation and buffering ability to withstand various degradation enzymes and to protect DNA from non-specific endolysosomal degradation.

### 21.2.2 Stability of Biologics

The stability of biologics is one of the most important issues when developing a controlled-release system. To ascertain the stability of biologics, especially proteins and peptides, during fabrication, storage, and release, various analytical techniques have been used. The secondary and tertiary structural integrity of the protein or peptide can be determined using circular dichroism spectroscopy and differential scanning calorimeter, and the primary structural integrity can be analyzed using high-performance liquid chromatography and mass spectroscopic techniques. Gel electrophoresis and size exclusion chromatography can be used to establish the presence and nature of aggregates of proteins and peptides formed during formulation or encapsulation, release, and storage. Specific bioassays are useful to verify the bioactivity of the protein or peptide released from the delivery system. In the case of mAbs, their surface interactions can be assessed using quartz crystal microbalance [16]. To determine the stability and structural integrity of the gene or DNA incorporated in the delivery system, the commonly used techniques include agarose gel electrophoresis and ultraviolet spectroscopy; their biological functionality can be evaluated by various cell transfection experiments [17].

## 21.3 FEASIBLE SYSTEMS FOR BIOLOGICS

A brief outline of some of the feasible parenteral controlled delivery systems used for delivering biologics has been described here. Table 21.1 presents findings of various controlled delivery systems for biotherapeutics.

### 21.3.1 Microspheres

Biodegradable microsphere is the most common feasible systems for parenteral delivery of biologics. Microspheres are small spherical particles with a diameter of 1 to 1000 μm. The biodegradable microsphere delivery systems for proteins and peptides help to maintain stability against chemical and enzymatic degradation, increase their plasma half-lives, and achieve a sustained release profile. Similarly, biodegradable microspheres for nucleic acid delivery offer enhancement in oligonucleotide pharmacologic effect by increasing the circulation lifetime and stability of the therapeutic gene and avoids potential risks of using viral vectors. One of the key factors in the design of injectable microsphere is the choice of suitable polymers. Biodegradable polymers are chosen over the nonbiodegradable counterpart because of the aforementioned advantages of biodegradable polymers. Different techniques used for microsphere manufacturing include spray drying, double emulsification solvent evaporation, and phase separation–coacervation. Each of them has its specific merits and demerits. The selection of a particular method of encapsulation depends on criteria that include optimal drug loading, minimal exposure of labile proteins to strong denaturing solvents, stability, controlled-release profile, high yield with desired particle size, intra- and interbatch reproducibility, and micromeritic

**TABLE 21.1 Controlled Delivery Systems for Bioactive Agents**

| Delivery Systems | Biologics Delivered |
|---|---|
| Microparticles | HIV-1 D-GPEi plasmid/pCMV-Luc plasmid [20], pCMV-Luc/pCI-Neo plasmid [21], BSA/pEGFP-N1 plasmid [22], HBV S/V1012 plasmid [23], SPf 66 malaria vaccine [24], hepatitis B antigen [25], lysozyme [26], insulin [27,28], calcitonin [29], hGH [30], IGF-1 [31] |
| Microcapsules | Insulin [32,33], FITC-BSA [34], ovalbumin antigen [35], BSA [36,37] |
| Nanoparticles | pDNA for mouse IL-10 [38], pCMV/beta-gal and pEGFP-C1 plasmid [39], luciferase reporter plasmid [40], IL-1Ra plasmid DNA, influenza HA vaccine [41], BMPs [42], VEGF [43] |
| Polymeric hydrogels and *in situ* gel-forming systems | Luciferase pDNA [44], pCMV-SPORTB-gel [45], pLUC/pEGFP [46], IL-2 [47], calcitonin [48], insulin [49,50], GH [51], steroidal hormones [52] |
| Nanogels | Antisense ODN,53 IL-10 [54] |
| Peptide nanofiber hydrogels | EGF [55], ODN [56], lysozyme [16], BSA [16,57], IgG [57,58], IGF-1 [58], VEGF [58], insulin [59] |
| Implants, Matrices | PDGF-BB [60], PDGF-encoding plasmid [61], VEGF [62], bFGF [63], rh-INF alpha-2a (IFN-α) [64], *Clostridium tetani* and *Clostridium novy* toxoids [65] |
| Liposomes | Insulin [66], leuprolide [66], met-enkephalin [66], octreotide [66], cytokines (IL-1, IL-2, IL-6, GM-CSF, and IFN-γ) 67] |
| Suspensions | Zinc-insulin suspension [68], rHir [69], plasma-derived factor IX, and INF-α [70] |
| Vesicular phospholipid gels | Erythropoietin [71], cetrorelix [72] |
| Resealed erythrocytes [73] | Insulin, erythropoietin, IL-2, IL-3, IFN-α, vaccine subunits, toxoids, model antigens |
| Composite delivery systems | TGF-β [74], BSA [75,76], BDNF and VEGF [77], HSP27 [78] |

BDNF: brain-derived neurotrophic factor; bFGF: basic fibroblast growth factor; BMP: bone morphogenetic protein; BSA: bovine serum albumin; CMV: cytomegalovirus; D-GPEi plasmid: codon-optimized DNA plasmid containing the Gag, Pol, and Env gene; EGF: epidermal growth factor; FITC: fluorescein isothiocyanate; FITC-BSA: FITC-conjugated BSA; GH: growth hormone; GM-CSF: granulocyte-macrophage colony-stimulating factor; HA: hemagglutinin; HBV: hepatitis B virus; hGH: human growth hormone; HIV-1: human immunodeficiency virus type 1; HSP: heat shock protein; IFN: interferon; IGF: insulin-like growth factor; IgG: immunoglobulin G; IL: interleukin; ODN: oligonucleotide; pCI-Neo: SIY antigen-encoding plasmid; pCMV Luc: luciferase-encoding plasmid driven by the CMV promoter; PDGF-BB: platelet-derived growth factor-BB; pDNA: plasmid DNA; pEGFP: enhanced green fluorescent protein-encoding plasmid; pLUC: luciferase-encoding plasmid; rHir: recombinant hirudin; spf66: synthetic peptide vaccine against *Plasmodium falciparum* malaria; TGF: transforming growth factor; VEGF: vascular endothelial growth factor.

propeprties [18]. Other than these considerations, an important requirement of microsphere delivery system is syringeability through hypodermic needles. Several microsphere preparations available commercially include Lupron depot, Posilac, Trelstar depot, and Decapeptyl [19]. Although a number of microsphere formulations are on the market, these injectable particulate delivery systems

possess two major limitations, initial burst release (rapid release of encapsulated drug) and very slow release after the initial burst period, which is known as "lag time" [10]. Whereas the initial burst release may cause adverse drug reactions, the lag time results in ineffective treatment because of an insufficient dose. Therefore, great attention is directed toward eliminating the occurrence of initial burst release and lag period or time to make these delivery systems clinically acceptable. Other factors such as incomplete release and instability of delicate biotherapeutics during fabrication and release are also important during the development of effective microparticle-based delivery.

### 21.3.2 Microcapsules

Although more complex than microspheres, microcapsules are receiving increasing interest as potential drug delivery systems. Microcapsules consist of two essential parts, the core and the coat. The core usually includes bioactive agents (protein, peptides, DNA, or entire cells) either in aqueous solution or in solid state with or without additives. The coat forms an inert diffusion barrier surrounding the core and should have desired coating properties such as solubility, permeability, flexibility, strength, and stability. The most commonly used biodegradable coating materials for microencapsulation include alginate [79], PLGA [32], collagen [80], and chitosan [81,82]. The incorporated drug can escape through the capsule coat by rupturing the wall, dissolution, melting, or diffusion [83]. Although several methods can be used to prepare microcapsules such as the double-emulsion method, organic phase separation, spray drying, and supercritical fluid technique [13,84,85], the stability of the active ingredient dictates the choice of a suitable method. A unique and novel method of formulating reservoir-type microcapsules has shown promise for encapsulating proteins and peptides. This method uses the interfacial phase separation technique, which helps to preserve the stability of proteins and peptides by preventing their exposure to an aqueous–organic interface [86].

### 21.3.3 Nanoparticles

Nanoparticles are defined as colloidal dispersion or solid particulate systems having a size in the range of 1 to 1000 nm [87,88]. The therapeutic agent can be distributed within the nanoparticle matrix or adsorbed or attached onto the matrix. Nanoparticles, including nanospheres and nanocapsules, are usually prepared by similar methods as those described earlier for microparticles, but in this case, the manufacturing parameters are tuned so that the particle size will remain in the nanometer range [13]. The commonly used methods for nanoparticle preparation are solvent evaporation, solvent diffusion, nanoprecipitation, ionic gelation or coacervation, double emulsification, and polymer coating using a variety of materials (e.g., polysaccharides, proteins, and synthetic polymers [PLGA, PLA, polycaprolactone]). By changing the preparation method, nanocapsules or nanospheres can be obtained. Nanocapsules exhibit a typical core-shell assembly wherein the drug is confined to a reservoir or within a cavity enclosed by a uniform polymer membrane or coating; in

nanospheres, the drug is homogenously dispersed in the matrix [89]. The aim of designing a nanoparticulate delivery system is to control the particle size, surface characteristics, and release profile of the incorporated biotherapeutic agent to maintain site-specific action and dosing regimen. Because of their small dimensions, nanoparticles can easily enter through the cell membrane compared with microparticles. The cellular uptake of nanoparticles is inversely proportional to their small dimensions; for example, particles with an average diameter of about 100 nm are phagocyted by cells 2.5 times more than particles having an average diameter of 1 μm [90]. Biodegradable polymeric nanoparticles have become an important delivery system because of their ability to maintain the stability of encapsulated drugs and to deliver a vast variety of therapeutic agents, including hydrophilic and hydrophobic drugs, peptides, proteins, vaccines, and other bioactive agents, to various organs for a prolonged period of time [91–94]. But the major problems associated with nanoparticulate delivery systems include particle aggregation, low loading capacity, high burst release, and clearance from the blood circulation by phagocytosis. To overcome these limitations, nanoparticles are often modified with polymeric surfactants or other modifiers to reduce aggregation, prevent burst release, and improve stability in the presence of plasma proteins [95–97].

### 21.3.4 Hydrogels

In recent years, hydrogel-based systems have been receiving increasing interest for the controlled delivery of hydrophilic biological macromolecules such as peptides [98,99], proteins [57,100], and DNA [101,102] because of their capacity to provide a protective environment and ability to control the diffusion by modulating the extent of cross-linking within the polymer matrix. A hydrogel can be defined as a cross-linked polymeric network that has the capacity to swell without dissolving in an aqueous environment. Hydrogels are usually stabilized through physical or chemical cross-linking between polymeric units forming a gel backbone and have porous morphology. Generally, at equilibrium, the hydrogels consist of about 60–90% fluid and only 10–30% polymer. Their high water content makes them compatible with proteins, living tissues, and DNA because of their structural resemblance to the various components of the body [103]. Classification of hydrogels is based on several features summarized by Hamidi et al. [104]. The classification can be based on the nature of polymers, method of preparation, physical structure, and responsiveness to external stimuli. Depending on the polymer source, hydrogels can be classified into three groups: natural, synthetic, and hybrid polymer–based hydrogels. Natural polymers may be neutral (dextran, agarose, pullulan), cationic (chitosan, polylysine,), anionic (alginic acid, hyaluronic acid, pectin, chondroitin sulfate, dextran sulfate), or amphipathic (collagen, fibrin, carboxymethyl chitin) in nature [104]. Although natural polymers possess inherent biocompatibility, their use is also coupled with a number of drawbacks, such as poor mechanical strength, large batch-to-batch variation, and contamination issues. Therefore, synthetic polymers have been increasingly used for preparation of hydrogels. Among the synthetic polymers, “smart polymers” containing various hydrophobic and hydrophilic blocks

have gained tremendous attention. These polymers can be tailormade with different physical and chemical properties, hydrophobicity or hydrophilicity, degradation rate, and duration as per the delivery need. Smart polymers can be classified according to the external stimulus they respond to such as temperature, phase, pH, light, enzyme, ionic strength, electromagnetic radiation, and so on. These polymers show instantaneous changes in their physicochemical properties in response to slight alterations in their microenvironment [105]. Injectable *in situ*–forming hydrogels offer several benefits over their implantable counterparts. For instance, they permit easy homogenous encapsulation of biotherapeutic agent and can form hydrogel *in situ*, avoiding the need for surgical implantation and explantation [51,105–107].

A number of phase-sensitive and temperature-sensitive polymers have received attention as parenteral controlled delivery vehicles for various protein- and peptide-based therapeutics. The advantages of smart polymer–based delivery systems include easy manufacturing, high loading capacity, and injectability [105]. In 1990, Ravivarapu et al. [108] patented the approach of dispersing drug molecules in biodegradable polymers dissolved in pharmaceutically accepted water miscible solvents. This depot-forming delivery system was known as Atrigel, and today seven products have been approved by the Food and Drug Administration based on the Atrigel technology [109].

Another class of smart polymers that has been extensively studied for controlled delivery of biologics is thermosensitive polymers. These polymers change their solubility in response to changes in temperature, and this property has been used to deliver various proteins and peptides. The major advantages of using these polymers as controlled delivery vehicles include no need of organic solvents that could damage the delicate structure of proteins or peptides, easy to prepare, injectable, biodegradable, and biocompatible; also, they do not need any surgical procedures for implantation and explantation [110,111]. The most widely used biodegradable polymers include PLGA and poly(ethylene) glycol (PEG)–based thermosensitive systems (Regel), Pluronics (PF-127), poly(organophosphazenes), and *N*-isopropyl acrylamide (NIPAAm) [111]. Hybrid polymers, the third type, are synthesized by combining both natural and synthetic polymers in an attempt to exploit the benefits of both classes. They can be prepared by blending or covalently crosslinking procedures. Some of these polymers include collagen-acrylate, alginate-acrylate, P(PEG-co-peptides), and alginate-g-(PEO–PPO–PEO) [104].

### 21.3.5 Nanogels

Although the main focus is on macroscopic hydrogels, nanogels and microgels are becoming increasingly popular in the field of controlled drug delivery for biologics. These colloidal systems have properties that are similar to macrogels, and they show additional benefits over nanoparticles. The combined characteristics of nanoparticles (nanometer in size) and hydrogels make them exclusive carriers for proteins, peptides, and DNA. Nanogel synthesis and drug loading are simple procedures and do not involve any organic solvent or harsh fabrication procedures that are detrimental to therapeutic agents. They have high drug loading capacity

and good transport and permeation capabilities because of their extremely small size (10–200 nm), they entrap and protect drug substances from immune cells, and they are easy to modify for targeting specific cells or tissues [53,112,113]. The widely studied hydrophobic core–forming polymers used for nanogel preparation include PLA, PLGA, polycaprolactone (PCL), polypropylene glycol, and polyhydroxybutyrate (PHB) [113]. Various natural polymers (dextrin, chitosan) and smart polymer–based nanogels have been successfully used for the delivery of DNA and proteins [54,114,115]. Some recent studies show the successful delivery of oligonucleotides across the blood–brain barrier (using a nanogel approach [53].

### 21.3.6 Peptide Hydrogels

Peptide hydrogel consists of periodic alternating hydrophobic and hydrophilic amino acids, which upon exposure to electrolyte solutions undergo spontaneous self-organization into nanosize fibers. These nanofibers further form highly hydrated hydrogels with the pore size ranging from 5 to 200 nm [16]. They also possess most appealing properties such as avoidance of toxic cross-linking agents during preparation, ease of injectability, nonimmunogenic nature, biodegradability, biocompatibility, and degradation to nontoxic end products [16]. These nanofibers hydrogels have been widely used to deliver proteins, peptides, DNA, and cells and as three-dimensional scaffolds for tissue engineering [55–58,116,117]. The release of protein from the peptide network is governed by charge and the size of encapsulated protein and their steric interactions with peptide network [57].

### 21.3.7 Liposomes

Liposomes are microscopic spherical vesicles that consist of an aqueous core enclosed by a lipid bilayers (or multilayer) of natural or synthetic phospholipids. The size of liposomes varies from as small as 20 nm (small unilamellar vesicles [SUVs]) to several micrometers (multilamellar vesicles [MLVs]) [118,119]. Because of the biphasic nature of liposomes, they can be used for delivery of both lipophilic and hydrophilic molecules, and depending on their solubility and partition coefficient, drug molecules get entrapped either in the aqueous phase or liposomal hydrophobic environment. The manufacturing protocol and the choice and amount of bilayer components dictate the release kinetics and encapsulation efficiency of a liposome. The drug-entrapping efficiency of liposomes depends on several factors, including the size of liposomes, types of phospholipids used for liposome preparation, and physicochemical properties of the encapsulated agent. For example, small SUVs have poor drug-loading capacity compared with MLVs. However, large unilamellar vesicles provide balance between size and drug-entrapping capacity. The established safety and efficacy profile of liposomes makes them attractive candidates for the delivery of hydrophobic or hydrophilic molecules, proteins, peptides, and vaccines. Furthermore, liposomes can be used for active targeting by attaching specific ligands to their surfaces. The most important feature of liposome-based delivery systems is attributed to the fact that the encapsulated

water-soluble therapeutic agent remains in the aqueous core with liposomal membrane protecting it against various destabilizing factors. Multivesicular liposomes or Depofoam particles have been used to circumvent the issues associated with conventional liposomes, resulting in sustained release delivery of protein or peptide drugs [66]. Liposomes are usually administered via the IV route, which poses certain issues. Liposomal interaction with high-density lipoproteins causes an early release of the encapsulated biotherapeutic agent [121]. In addition, because of the rapid uptake by the reticuloendothelial system, the overall circulation time of liposomes gets reduced [122,123]. PEG grafting on the liposome surface can help to counteract the issue with serum protein opsonization and interaction with mononuclear phagocytic cells. This helps increase the retention time of liposomes in the blood [124]. Liposomes are often combined with other controlled delivery systems to obtain the advantageous properties of both. Polymer–liposome composite systems are developed so as to provide enhanced stability to the liposomes and to control the *in vivo* release profile of encapsulated bioactive agents [125].

### 21.3.8 Vesicular Phospholipid Gels

This delivery system consists of concentrated semisolid, aqueous phospholipid dispersions of vesicular morphology [71,126]. They are usually prepared by a process known as "forced hydration" of phospholipids in the presence of a comparatively small amount of water [71]. The size, morphology, and structure of the vesicles depend on the phospholipid content [127,128]. Vesicular phospholipid gel (VPGs)s can be used as intermediates for liposomes and are converted into liposome dispersions upon dilution. Some of the advantages of VPGs over traditional liposomes include better encapsulation efficiency because more drug gets entrapped or localized within and in between the vesicles of polymer matrix. Also, they are easy to manufacture and scale up; there is no use of organic solvent, eliminating harmful effects on delicate proteins and peptides; and the delivery matrix is biocompatible [71].

### 21.3.9 Suspensions

This is the most common and widely used dosage form in parenteral controlled delivery systems. After SC administration, the drug incorporated in aqueous or oil suspension forms a depot at the site of injection, which acts as a reservoir. The incorporated molecule is released slowly and continuously depending on its aqueous solubility and dissolution of particles into surrounding tissue fluid [129]. One of the classic examples of this delivery system is a insulin or zinc–insulin suspension used for the treatment of diabetes.

### 21.3.10 Implantable Delivery Systems

Implants are small rod-shaped or cylindrical devices that are either used for systemic or local long-term delivery of biologics and small molecule drugs [9]. For systemic

delivery, they are usually placed intramuscularly or in SC tissue from where the drug enters into blood circulation; for local effects, implants are placed in specific sites in the body. The benefits of using implants for controlled delivery include easy manufacturing, tunable drug release, and ability to be removed in case of any adverse effects. A few nonbiodegradable implants are commercially available for long-term controlled delivery of steroids [130–133]. Implantable systems provide many advantages such as prolonged activity and targeting. Among the diverse technology available for the controlled delivery of biologics, delivery systems based on nonbiodegradable, hydrophobic polymers are the most successful. For example, the Norplant system is a reversible contraceptive device consisting of six small matchstick-sized capsules that are placed just beneath the skin of the upper arm for the controlled delivery of progestin over a 5-year period [134]. A new approach of osmotic implantable delivery systems that was described in 1955 has become a widely accepted tool for controlled delivery of various biotherapeutics agents [135]. An osmotically driven subcutaneously implantable delivery system has been designed for the delivery of a peptide, leuprolide, over a year-long duration for palliative treatment of prostate cancer [136]. Another method includes an SC infusion patch containing an exterior protein or peptide pump reservoir that is designed to release protein continuously to achieve a constant level for a prolonged period [137]. Some of the important characteristics of an ideal pump-based delivery system include an accurate and precise delivery rate, easy to program depending on the need of the patient, reliable, safe, free from inflammatory reactions after implantation, no leakage or overdosing, long reservoir life, easy to use by both the patient and health care professional, and sufficient long battery life [138]. Although nonbiodegradable implants are developed for this purpose, their patient acceptance is low because of the need for a large-bore needle for implantation, need for medical professionals, discomfort, and the surgical insertion and retrieval procedures involved. Additionally, the cost of the implant production is high, and the instability of encapsulated drug during manufacturing is still a major issue. In the case of implants, fibrous capsule formation is the most common foreign body reaction observed that gives rise to undesirable effects on drug release from the implant [139]. Biodegradable implants provide a benefit of a single procedure (no explantation), and a large number of PLGA- and PLA-based implants have been evaluated for protein and peptide delivery [140,141]. These implants are degraded into acidic byproducts and are naturally eliminated in the body. Recently, an agarose hydrogel–based implant system has been developed by Toussaint et al. [142] for the delivery of DNA vaccine in cattle.

### 21.3.11 Resealed Erythrocytes

Red blood cells, or erythrocytes, are the most abundant cells in the body and have the potential for controlled delivery of various biotherapeutics. They are biocompatible and biodegradable carriers, are nonimmunogenic, and possess very long circulation half-lives. They can protect the incorporated drug from immunologic detection and enzymatic degradation, do not require any chemical modification for entrapment of

drug molecules, and have controllable lifespan. It is also possible to obtain ideal zero-order release kinetics using resealed erythrocytes [11,73]. The drug release from the erythrocyte can take place by (1) passive diffusion; (2) membrane-associated carrier transport; (3) phagocytosis by macrophages, leading to accumulation of drug into macrophages followed by slow release; or (4) accumulation into lymph nodes after SC administration with subsequent hemolysis and slow release of the incorporated molecule [143].

### 21.3.12 Composite Delivery Systems

A conventional single delivery system may suffer from some restrictions for the delivery of therapeutic agents; therefore, to compensate for the disadvantages associated with a single system, combinations of two or more delivery systems have been explored. With the use of composite delivery systems, it is possible to tune the release period and duration as per the need. The most widely studied combination delivery systems for controlled protein delivery include microparticle–hydrogel, liposome–hydrogel, and microcapsule–nanoparticle [74–78,144,145]. The limitations of liposomal delivery system, such as instability, short half-life, and rapid clearance from the body, can be overcome by using a liposome– hydrogel approach. The new composite delivery system can help to improve liposome stability, and the drug release can be controlled while preserving the bioactivity of the incorporated molecule [146].

## 21.4 FUTURE DIRECTIONS

It is evident by the progress in new drug delivery technologies that much attention has been devoted toward the way in which biologics are delivered. Present efforts in the field of delivery of biologics have accelerated and widened the possibility of their use with therapeutic agents for treatment of various chronic disorders. From the times when achieving a zero-order release profile was just an imaginary concept and controlled release technology was known only to a few scientists, it has now been established widely and has gained significant applications in a variety of fields ranging from gene therapy to tissue engineering. Increasing numbers of publications, patents, and commercial availability of controlled delivery products substantiate their significant advancement. Many pharmaceutical industries are now focusing on the development of new delivery systems for controlling the release of novel biologic agents. The concept of using specific targeting moieties and feedback control mechanisms has shown tremendous growth over the past few decades. The two most appealing controlled delivery systems that will be preferred in the future include targeted delivery systems and feedback-controlled delivery systems. Another significant advancement in the field of controlled delivery is the use of smart polymers. These polymer-based delivery systems are able to control the release of incorporated molecules in response to external stimuli, rendering them ideal for delivery of various biologics, including proteins and peptides, genes, and vaccines as per the needs of a patient [105].

# Routes of Delivery for Biological Drug Products

DARRELL J. IRVINE, XINGFANG SU, and BRANDON KWONG

## 22.1 INTRODUCTION

Unlike conventional small molecule drugs, many of which can be formulated effectively with excipients to avoid degradation in the stomach and that exhibit reasonably efficient uptake through the gastrointestinal (GI) tract, biological drugs may exhibit lower stability and a greater sensitivity to enzymatic degradation, making oral delivery problematic. Thus, the majority of biologics are currently administered through subcutaneous (SC) or intramuscular (IM) injection or via intravenous (IV) infusion. Recent advances in delivery of traditional biologics include methods to increase the acceptable volume of drug solutions that can be administered subcutaneously. In addition, a number of alternative routes of administration for biologic drug products are being intensively investigated at the preclinical and clinical stages, such as intranasal, pulmonary, transcutaneous, and other routes, with some first examples of products recently licensed. This chapter reviews current methods in use for marketed biologics and advanced approaches undergoing clinical testing.

## 22.2 CONVENTIONAL ADMINISTRATION OF BIOLOGICAL DRUG PRODUCTS

### 22.2.1 Systemic Administration of Biologics

Intravenous delivery has traditionally been the standard route of administration for biologic drugs such as antibody or recombinant protein therapies. Although conventional small molecule drugs are frequently delivered orally, providing the highest levels of cost effectiveness, patient comfort and compliance, and ease of administration, biologic drugs have proven to be extremely difficult to deliver in a similar manner. The acidic pH and digestive enzymes present in the GI tract can result in

significant degradations of biologic drugs. In addition, biologics can be subject to an extremely poor rate of absorption through the GI tract, a problem that may only be exacerbated by their formulation with carriers or vehicles aimed at resisting degradation [1]. On the other hand, IV delivery of biologics provides the principal advantages of (1) achieving 100% initial bioavailability with no loss of drug at the point of entry into the body and (2) the immediate dissemination of the drug through the systemic circulation, rapidly accessing all vascularized tissues throughout the body. Furthermore, IV administration allows for significantly higher injection volumes (and consequently higher therapeutic dosages) than other parenteral routes such as SC or IM injections. The following section describes examples of biologic drugs currently approved for IV administration and examines the disadvantages associated with IV delivery that have motivated the development of alternative (both local and systemic) routes of administration.

***22.2.1.1 Clinically Approved Biologics for Intravenous Delivery*** Monoclonal antibodies (mAbs) comprise the majority of the biologic drugs currently approved for IV administration. The first mAb therapy to achieve clinical approval from the Food and Drug Administration (FDA) was muromonab-CD3 (Orthoclone OKT3) in 1985, prescribed to prevent acute allograft rejection in organ transplant patients by suppressing the antitransplant T-cell response [2]. After the successful introduction of muronomab-CD3, a wide variety of other mAbs have now reached market approval in the United States and globally. Representative examples of mAbs approved for IV infusion are outlined below in Table 22.1 (part A) along with brief descriptions of the biological activity of each antibody and the indications for which they are prescribed. These include basiliximab, daclizumab, infliximab, and a large number of other mAbs that have been developed predominantly for the purpose of cancer therapy, beginning with the 1997 approval of rituximab, an anti-CD20 antibody [3]. Although certain anticancer mAbs directly target and bind to surface proteins expressed on tumor cells (e.g., rituximab, alemtuzumab, trastuzumab) [4–7], others target immune pathways and angiogenic factors in order to inhibit the progression of tumors (e.g., ipilimumab, bevacizumab) (see Table 22.1). In addition to pure mAbs, a small number of antibody–toxin conjugates using chemical agents or radioisotopes have also been approved for the treatment of various lymphomas (causing targeted cytotoxicity), as well as a limited number of recombinant cytokines such as interleukin-2 (IL-2, Proleukin) and interferon $\alpha$-2b (IFN-$\alpha$-2b), which mediate immunostimulatory antitumor responses.

Whether biologic therapies are used to treat hematologic (e.g., lymphoma) or nonhematologic indications (e.g., solid tumors and autoimmune disorders), IV infusion enables the rapid systemic distribution of the antibody or biologic agent without loss of bioavailability. Moreover, IV injected therapeutics can be rapidly dispersed to solid tumors in internal organs that may otherwise be inaccessible for local administration without surgery, as well as undetectable micrometastases that may have spread throughout the body. From a practical perspective, antibody therapy for cancer frequently requires large therapeutic doses (e.g., 8 mg/kg for trastuzumab; 375 mg/m$^2$ for rituximab) [8,9], necessitating an injection volume for complete

**TABLE 22.1 Representative Biologic Therapies Administered by Conventional Routes**

| Drug Name | Biological Agent | Indications |
|---|---|---|
| | | *A. Intravenous Infusion* |
| Muromonab-CD3 | Anti-CD3 | Organ transplant rejection |
| Basiliximab | Anti-IL-2Rα | Organ transplant rejection |
| Infliximab | Anti-TNFα | Rheumatoid arthritis, Crohn's disease, ulcerative colitis, psoriasis, ankylosing spondylitis |
| Rituximab | Anti-CD20 | Non-Hodgkin's lymphomas, rheumatoid arthritis |
| Alemtuzumab | Anti-CD52 | B-cell chronic lymphocytic leukemia |
| Cetuximab | Anti-EGFR | Colorectal cancer, head and neck cancer |
| Trastuzumab | Anti-HER2 | Metastatic breast cancer |
| Bevacizumab | Anti-VEGF | Colorectal cancer, lung cancer, glioblastoma, metastatic renal cell cancer, non–small cell lung cancer, age-related macular degeneration |
| Ipilimumab | Anti-CTLA-4 | Advanced melanoma |
| Brentuximab vedotin | Anti-CD30/MMAE conjugate | Hodgkin's lymphoma, anaplastic large cell lymphoma |
| Iodine Tositumomab | Anti-CD20/iodine-131 ($^{131}$I) | Follicular lymphoma |
| Gammagard Liquid | Human immune globulin | Primary immunodeficiencies |
| Proleukin | IL-2 | Melanoma, renal cell cancer |
| Abatacept | CTLA-4/Fc fusion | Rheumatoid arthritis |
| Intron A | IFN-α-2b | Malignant melanoma |
| Denileukin diftitox | IL-2/Diphtheria toxin conjugate | Cutaneous T-cell lymphoma |
| Pegloticase | PEGylated uricase | Chronic gout |
| Hemacord | Hematopoietic progenitor cells | Hematopoietic/immunologic reconstitution |
| Provenge | Activated autologous leukocytes | Hormone-refractory prostate cancer |
| | | *B. Subcutaneous or Intramuscular Injection* |
| Adalimumab | Anti–TNF-α | Rheumatoid arthritis, juvenile arthritis, Crohn's disease, ankylosing spondylitis, psoriasis |
| Golimumab | Anti–TNF-α | Rheumatoid arthritis, psoriasis, ankylosing spondylitis |
| Denosumab | Anti-RANKL | Osteoporosis, bone metastases from solid tumors |
| Certolizumab pegol | PEGylated anti–TNF-α | Rheumatoid arthritis, Crohn's disease |

(*continued*)

**TABLE 22.1** (*Continued*)

| Drug Name | Biological Agent | Indications |
|---|---|---|
| Gammagard Liquid | Human immune globulin | Primary immunodeficiencies |
| Etanercept | TNF antagonist | Rheumatoid arthritis, juvenile arthritis, ankylosing spondylitis, psoriasis |
| Anakinra | IL-1R antagonist | Rheumatoid arthritis |
| Abatacept | CTLA-4/Fc fusion | Rheumatoid arthritis |
| ActImmune | IFN-γ-1b | Chronic granulomatous disease, osteopetrosis |
| Roferon-A | IFN-α-2a | Chronic hepatitis C, hairy cell leukemia, chronic myelogenous leukemia |
| Intron A | IFN-α-2b | Chronic or acute hepatitis C, chronic hepatitis B, hairy cell leukemia, follicular lymphoma, Kaposi's sarcoma |
| PEGasys | PEGylated IFN-α-2a | |
| PEG-Intron | PEGylated IFN-α-2b | Chronic hepatitis C, chronic hepatitis B |
| Avonex | IFN-β-1a | Chronic hepatitis C |
| Betaseron | IFN-β-1b | Multiple sclerosis |
| Allergen immunotherapy | Allergen vaccination | Multiple sclerosis<br>Allergic rhinitis, allergic asthma, conjunctivitis, insect allergy |
| | | *C. Local Site Injection* |
| Pegaptinib | PEGylated anti-VEGF aptamer | Age-related macular degeneration (eye) |
| Ranibizumab | Anti-VEGF-A | Age-related macular degeneration (eye) |
| Catumaxomab | Anti-CD3/Anti-EpCAM | Malignant ascites in metastatic cancers (intraperitoneal) |
| Carticel | Autologous chondrocytes | Cartilage replacement (knee) |
| Laviv | Autologous fibroblasts | Cosmetic filling of wrinkles (facial) |
| | | *D. Oral Ingestion* |
| None approved in the United States | | |

EGFR: epidermal growth factor receptor; EpCAM: Epithelial cell adhesion molecule; IFN: interferon; IL: interleukin; PEG: poly(ethylene glycol); RANKL: Receptor activator of nuclear factor kappa B ligand; TNF: tumor necrosis factor; VEGF: vascular endothelial growth factor.

solubilization of the antibody that can only be administered IV. Notably, Proleukin therapy requires a significantly lower dosage than antibody therapies (0.037 mg/kg per dose) [10], but the systemic infusion of Proleukin is associated with severe adverse effects that can be potentially fatal (particularly capillary leak syndrome in internal organs, causing hypotension and reduced organ perfusion), thus requiring inpatient administration. Nevertheless, despite a clear motivation for developing alternative routes of injection, IV delivery remains the only approved route of administration for Proleukin, as SC dosing regimens aimed at optimizing therapeutic efficacy with minimal systemic toxicity have yet to achieve clinical approval [11]. Therefore, IV delivery remains the standard and optimal route of administration for the biologic therapy of cancer.

***22.2.1.2 Intravenous Delivery of Cell-Based Therapies*** There are currently only four approved biologic drug products that are classified as "cellular therapies" by the FDA (distinct from cell or tissue transplantations) [12]. Two of these approved cellular products, Hemacord and Provenge, are administered via IV infusion. Hemacord involves the transplantation of hematopoietic progenitor cells, isolated from donor cord blood, into patients requiring hematopoietic or immunologic reconstitution caused by hematopoietic disorders or a previous myeloablative therapy. Because the recommended minimum dose is 25 million cells/kg [12], IV infusion represents the only feasible option for the injection volume required, as well as for rapid systemic dispersion of the cell therapy. Similarly, Provenge, which consists of autologous leukocytes that are antigen primed and activated *ex vivo* for the treatment of metastatic prostate cancer, has a minimum dose of 50 million cells suspended in a 250-ml volume, so IV delivery remains the only practical option [12]. Furthermore, IV delivery enables the activated antitumor leukocytes to reach the prostate and lymphoid organs as quickly as possible (without necessitating surgery) while potentially allowing for targeting of metastases of the primary prostate tumor.

***22.2.1.3 Limitations of Intravenous Delivery of Biologics*** The case of Proleukin described illustrates one of the primary limitations of IV delivery: the potentially toxic side effects in nontarget organs that can be subjected to high levels of intravenously administered biologic drugs. Another recombinant cytokine therapy that has proven extremely difficult to optimize in terms of balancing efficacy with minimal toxicity has been the use of tumor necrosis factor α (TNF-α) as an immunostimulatory anticancer treatment. TNF-α is believed to act preferentially on tumor endothelium, inducing hyperpermeability that results in hemorrhagic necrosis of the tumor tissue [13]. However, systemic exposure to high levels of TNF-α can cause severe toxicities such as hypotension and septic shock–like syndrome [14]. For this reason, the use of TNF-α in cancer therapy has been limited to isolated limb perfusions (ILPs), approved in Europe for the treatment of soft tissue sarcomas and metastatic melanoma in the extremities. The procedure consists of surgically clamping major blood vessels and ligating collateral vessels to or from the limb followed by perfusion of TNF-α in combination with chemotherapy into the isolated tumor-bearing limb. Although TNF-α ILP therapy has achieved robust

response rates [13], this treatment is limited by the clinical specialization required to provide such therapy and its applicability only to cancers located in limb extremities. More generally, this illustrates a clear motivation to develop alternative forms or routes of administration, to increase the specificity of therapy delivery to localized tumor tissues, and to reduce the severity of systemic toxicity.

Another limitation of the IV infusion is the potential for rapid clearance of the therapeutic agent. Clearance of biologics from the circulation can occur either by renal filtration or nonspecific binding and uptake (e.g., endothelial pinocytosis) [15]. A short circulatory half-life can necessitate frequent injections, from weekly to daily doses, thus increasing the patient's discomfort, overall expense of the treatment regimen, and risks of patient noncompliance. Although antibody therapies (whole IgG) can persist in circulation for days or weeks because of their large size and recycling via neonatal Fc receptors (FcRns), recombinant cytokines and antibody fragments (e.g., FAb′) commonly persist for much shorter circulation times (typically minutes to hours) [16–18]. To increase the plasma half-life, a strategy known as PEGylation was developed, in which the hydrophilic polymer poly(ethylene glycol) (PEG) is covalently conjugated to the therapeutic. This increases the hydrodynamic size of the therapeutic molecule, thereby reducing its rate of renal clearance and significantly enhancing persistence in the circulation, up to several hundred-fold (Fig. 22.1a and b) [19,20]. Moreover, PEGylation has been found to reduce the immunogenicity of biologic drugs and their nonspecific binding to nontarget cells, decreasing the incidence of infusion-site reactions [21]. Successful examples of FDA-approved PEGylated biologics include Pegloticase (uric acid–metabolizing enzyme) for the treatment of chronic gout; PEGasys (INFα-2a), an antiviral therapy used to treat hepatitis B and C; PEGintron (INFα-2b) for hepatitis C; and Certolizumab pegol (anti-TNF-α FAb′ fragment) used to treat autoimmune Crohn's disease. Of these, only Pegloticase has been approved for IV administration to date, but the others have been approved for SC injection and continue to be investigated for possible regimens of IV delivery [22].

A variety of other promising strategies are currently under preclinical investigation for increasing the serum half-life or tuning the pharmacokinetics (and subsequent efficacy) of antibody therapies. These include the engineering of increased affinity of the Fc region of IgG antibodies to neonatal FcRn and the engineering of net charge on antibodies [23]. IgG binding to the FcRn enhances serum half-life by enabling antibodies to be internalized into cells, endosomally recycled to the cell surface, and released back into plasma, in essence protecting the antibody from proteolytic or clearance processes that occur extracellularly during plasma circulation. Preclinical studies have now established that improving FcRn affinity can increase serum half-life in nonhuman primates (Fig. 22.1c and d) [24,25].

### 22.2.2 Subcutaneous Administration of Biologics

The major problems of toxicity and rapid clearance after the IV delivery of biologics are both related to the near-immediate systemic availability of the infused therapy. In the successful examples noted earlier, such rapid availability may be necessary to

**FIGURE 22.1** Strategies for prolonging the *in vivo* half-life of biologics. (a) Conjugation of different chain lengths of polyethylene glycol (PEG) to a radiolabeled Fab' fragment increases its serum half-life after intravenous (IV) injection in rats [17]. (b) Comparison of the serum half-lives of PEGylated (square symbols) or non-PEGylated (circle symbols) interferon-β-1a (IFN-β-1a) in rhesus monkeys after intramuscular (filled symbols) or subcutaneous (open symbols) administration [18]. (c, d) Increased serum half-lives of anti–vascular endothelial growth factor (VEGF) and anti–epidermal growth factor receptor (EGFR) antibodies that were engineered (Xtend-VEGF, Xtend-EGFR) for enhanced affinity to neonatal Fc receptor (FcRn) [25].

achieve therapeutic efficacy; however, many biologic drugs benefit from a slower pharmacokinetic distribution through the body (while maintaining systemic availability). In addition, IV infusion is accompanied by the risk of catheter-mediated infection, causes significant pain and discomfort, and requires supervised inpatient administration. For more patient-friendly administration and to enable self-administration, SC delivery of biologics is of great interest. A number of licensed biologics are currently administered SC, and the success of this route of administration has been critical for biologic therapies used in managing chronic disease states or symptoms. These include a variety of autoimmune diseases (e.g., rheumatoid arthritis, ulcerative colitis, Crohn's disease, others) and other chronic indications such as chronic granulomatous disease or primary immunodeficiencies in which continuous biologic therapy is essential to compensate for chronically immunocompromised patients (refer to Table 22.1, part B). The ability to self-administer therapy via SC injection, as opposed to requiring the continual inpatient administration of IV infusions, provides an enormous benefit to patient quality of life, particularly for biologic drugs with short circulatory half-lives that may require frequent dosing.

Another context in which the use of SC injection is able to improve on IV delivery is in the case of biologic drugs with severe toxicity after systemic infusion. For example, recombinant cytokine therapies such as α and β INFs can provide therapeutic benefits in a number of diseases, including various cancers, hepatitis B and C, and multiple sclerosis [26–28], but the IV delivery of such therapies can lead to adverse events after rapid systemic dissemination of the therapeutic. SC administration provides an advantage over IV infusion by creating a relative depot effect at the site of injection: the time required for the therapeutic to drain into systemic circulation effectively prolongs the half-life of the agent *in vivo* while simultaneously lowering the peak drug level experienced by various compartments, thus reducing the frequency of dosing required as well as reducing the frequency or severity of adverse events [29]. The following section briefly reviews examples of biologic drugs in which SC injection has been approved as an alternative to or improvement upon IV infusion and discusses some unique limitations associated with the SC delivery route.

***22.2.2.1 Clinically Approved Biologics for Subcutaneous Injection*** For biologic drugs that have short half-lives *in vivo*, the availability of a formulation for self-administered SC injection provides an obvious benefit to patient quality of life. This is particularly true for the management of chronic or age-related diseases requiring a lifelong duration of therapy. For example, Anakinra (Kineret) therapy of rheumatoid arthritis requires a daily injection of 100 mg per dose [30]. Similarly, a number of TNF-α antagonists have been developed and licensed for self-administered SC injection in the treatment of rheumatoid arthritis, Crohn's disease, and other chronic autoimmune conditions (see Table 22.1, part B). In some cases, biologic therapies were first approved for IV administration before subsequent approval for self-administered SC injection has been obtained. For example, Abatacept (Orencia) and Gammagard Liquid (human immune globulin infusion) were initially prescribed

for periodic IV infusion until subsequent studies established that SC administration could provide comparable efficacy with a noninferior safety profile, including measures of the frequency and severity of infusion-site reactions, pain or tolerability, frequency of serious adverse events, and immunogenicity [31]. As a result, both abatacept and Gammagard were approved in 2011 for self-administered SC injection.

Recombinant cytokines such as α and β IFNs have proven successful in the clinical treatment of a wide variety of conditions (see Table 22.1). Whereas IFNs β-1a (Avonex) and β-1b (Betaseron) are administered solely via SC injection (for the treatment of multiple sclerosis) [32,33], the administration route for IFN-α-2a or -2b depends on the disease under treatment. For example, IFN-α-2a and -2b (either in PEGylated or non-PEGylated formulations) are only approved for SC injection in the treatment of hepatitis C, but IFN-α-2b is administered in a mixed regimen (IV induction followed by SC maintenance) for high-risk melanoma patients. While the toxicity of IFN-α-2b therapy is significant, particularly during the IV dosing phase, studies have suggested that the higher peak levels of plasma concentration obtained by IV delivery are necessary for the overall therapeutic efficacy of the treatment [34,35]. This example highlights the difficulty in achieving a tolerable but efficacious therapy with such potent biologic drugs and how tuning the regimen of drug delivery can help to optimize biodistribution and pharmacokinetics in order to reach the required therapeutic window.

***22.2.2.2 Limitations of Subcutaneous Delivery of Biologics*** Although SC injections can be used to achieve a flatter pharmacokinetic profile (a lower peak plasma concentration but a more prolonged duration at an efficacious level), a limitation of the SC route is the injection volume that can be administered without pain in humans, at a maximum of approximately 2 to 2.5 ml of fluid [29]. For regimens of some biologics, such as therapeutic antibodies in oncology applications, the most concentrated form of the drug that can be prepared in a stable, injectable form requires a dosing volume of 5 ml, making traditional SC injection problematic [36]. To overcome this volume limitation, one strategy currently in phase 3 clinical trials is the use of recombinant human hyaluronidase to locally digest hyaluronic acid, a key polysaccharide component of the extracellular matrix (ECM) in connective tissues [37]. When hyaluronidase is co-injected with biologics, it generates nanoscale porosity in the local ECM allowing rapid draining of fluid from the injection site and permitting much larger volumes of solution to be injected without pain; the matrix self-repairs within about 24 h, making the alterations only transient [38]. For example, preclinical studies in animal models have demonstrated that the addition of hyaluronidase to SC injections of a tracer dye, a fluorescently labeled dextran, and fluorescently labeled latex nanoparticles enhanced the immediate dispersion of these model agents [37,38]. Several approved mAbs in oncology (Herceptin, rituximab) that are currently given as IV infusions are being tested with this modified administration strategy to improve patient compliance with prolonged (>1 year) maintenance therapies that are indicated in conditions such as early breast cancer treatment [36]. Thus, even traditional administration routes are benefiting

from innovations in drug delivery or drug administration that may be broadly applicable to many therapeutics.

Although SC (or IM) injections enable patients to self-administer biologic therapies, thus removing the inconvenience and expense of inpatient care, the potential severity of local injection site reactions (and associated pain) remains a significant limitation of this delivery route. Common injection site reactions include erythema, edema, hematoma, swelling, pruritus, local infection, and pain [30,31,39]. Occasionally, more severe symptoms caused by anaphylactic reactions can also occur. Because SC therapies usually require frequent dosing (daily to weekly), the repeated manifestation of these symptoms often leads to poor patient adherence to the prescribed regimen of therapy. Even in the absence of significant pain, psychological reactions associated with needle injections can greatly reduce patient compliance, particularly in the case of pediatric patients [40,41]. This has motivated ongoing studies to develop alternatives to traditional needle injection for the SC delivery of biologics.

The use of automated injection devices (autoinjectors) was first developed for insulin injection for patients with chronic diabetes. Autoinjectors have now been shown to improve patient compliance in a variety of self-administered therapies compared with traditional, manually injected syringe-and-vial formulations [41]. Besides improving the convenience and ease of injection, autoinjectors such as the RebiJect and BetaJect injectors (for the SC IFN-β therapy of multiple sclerosis patients) or the SmartJect injector (for anti-TNF therapy of rheumatoid arthritis patients) have demonstrated lower incidences of injection site reactions and reduced pain [39]. Needle-free injection devices for SC delivery represent a further advance in delivery technology, such as the "cool.click" device developed for the administration of human growth hormone therapy in patients with growth hormone deficiency. The needle-free cool.click device uses a high-pressure nozzle to disperse a liquid formulation of growth hormone through the skin into the SC tissue [40]. Use of this device was particularly preferred among pediatric patients and led to overall increased compliance to prescribed regimens of therapy [42].

Despite continuing efforts to develop new technologies for SC delivery, the majority of SC biologics still require manual injection. Given the limitations associated with this delivery route, this has motivated increasing investigation into alternative delivery routes for currently established SC therapies. For example, sublingual delivery has been extensively studied as an alternative to SC injection for allergen immunotherapy of patients with allergic rhinitis or asthma [43,44]. Although the comparative efficacy of sublingual versus SC administration of allergen immunotherapy has not been fully established, sublingual therapy is highly attractive because of its improved safety profile and pain-free delivery [43]. Additional alternatives to SC delivery, such as transdermal patches, intranasal or pulmonary administration, or other mucosal routes are also discussed in the following sections.

### 22.2.3 Local Injection of Biologics

The majority of parenterally delivered biologics are injected intravenously, subcutaneously, or intramuscularly to allow systemic distribution of the drug to all

vascularized tissues. Although these delivery routes are advantageous for diseases and clinical conditions that affect internal organs or widespread tissues throughout the body, they can also result in suboptimal levels and kinetics of local drug concentration in the case of highly localized diseases. For example, diseases of the brain are especially difficult to treat via the systemic delivery of biologic drugs because biologics (and even the majority of small molecule drugs) are too large and hydrophilic to pass through the low permeability of the blood–brain barrier (BBB). Furthermore, the systemic delivery of biologic drugs can result in adverse side effects in off-target organs, which might be completely avoided by a locally restricted therapy. Therefore, for a small number of indications in which the affected tissues are accessible (with or without surgery), the local injection of biologics has been approved or is currently under development.

***22.2.3.1 Locally Injected Biologic Drug Therapies*** For the treatment of highly localized diseases, the direct injection of biologics into the affected tissue can be highly advantageous (Table 22.1, part C). A primary motivation for the local injection of biologic drugs is to minimize systemic exposure and the subsequent toxicities that may result. An example of this is the intravitreal injection (directly into the eye) of anti–vascular endothelial growth factor (VEGF) antagonists for the treatment of age-related macular degeneration (AMD). Pegaptinib (Macugen), an RNA aptamer that targets VEGF, and the anti-VEGF mAbs bevacizumab and ranibizumab have all demonstrated the ability to slow the progression of AMD [45]. However, the systemic infusion of VEGF antagonists can potentially disrupt the normal functions of VEGF in healthy vasculature throughout the body, leading to increased risks of thromboembolic events, hypertension, and impaired wound healing [45]. Early clinical studies showed that intravitreal injections of VEGF antagonists had an improved safety profile compared with IV infusion, with reduced frequency of systemic adverse events [46]. Therefore, intravitreal injection remains the only approved route of administration for these VEGF antagonists in the treatment of AMD.

Another important motivation for the local injection of biologic therapy is to maximize the local concentration of therapy, improving the efficacy of treatment on a specific tissue or organ. For example, the bispecific antibody catumaxomab (anti-CD3/anti-epithelial cell adhesion molecule EPCAM) is injected intraperitoneally for the treatment of malignant ascites resulting from epithelial, gastric, or ovarian cancers [47]. The EPCAM specificity targets EPCAM-expressing epithelial tumor cells that have invaded the peritoneal cavity. Importantly, EPCAM expression is found in 70–100% of cases of malignant ascites, and the (non-tumor) peritoneal cavity itself is lined with EPCAM-negative mesothelial cells, enabling a high level of specificity of tumor binding [48,49]. Furthermore, preclinical pharmacokinetic studies confirmed that intraperitoneal (IP) administration of catumaxomab produced high local concentrations of the antibody in the ascites fluid while significantly limiting systemic exposure (<5% detectable in plasma), a critical finding given the potential toxicity of systemic anti-CD3 stimulation [50,51]. Subsequent clinical studies demonstrated potent therapeutic efficacy in activating antitumor immune

responses, eliminating tumor cells from the ascites fluid, and prolonging overall survival. This led to the approval of Catumaxomab for IP injection in the United States and Europe, with an escalating four-dose regimen up to a maximum dose of 150 μg [47]. In contrast, a phase I study of intravenously administered catumaxomab for the treatment of non–small cell lung cancer observed systemic dose-limiting toxicities at a dose of 5 μg, thus demonstrating a clear advantage for local injection [52].

Another indication where the local delivery of biologic drugs is currently under extensive study is in the treatment of glioblastoma and other brain malignancies. Effective therapy of brain tumors is especially difficult because of the tight endothelial cell junctions that form the BBB, which blocks the diffusion of molecules between circulatory vessels and cerebrospinal fluid. Although some small hydrophobic drugs may be able to penetrate this barrier, biologic agents such as recombinant proteins and antibodies are too large and hydrophilic, so the systemic infusion of such therapies is unable to reach brain malignancies [53]. Therefore, drug delivery into the brain requires surgical assistance: by the local implantation of controlled-release devices, by catheter-mediated infusion into the brain, or by "convection-enhanced delivery" (a gradient-driven delivery via intracranially implanted microcatheters) [54,55]. A variety of targeted toxin–biologic conjugates have now been tested clinically and preclinically using these methods of local intracerebral infusion, including a bispecific ligand-directed toxin that binds to tumor-overexpressed endothelial growth factor (EGF) receptor and urokinase plasminogen activator receptor, and a recombinant fusion protein of the cytokine TGF-α (also binding EGF receptor) with a *Pseudomonas* exotoxin [56,57].

Local injection is also under investigation as a delivery method for the biologic treatment of osteoarthritis and other joint disorders. After its success in the treatment of rheumatoid arthritis, Anakinra, a recombinant IL-1 receptor antagonist, has been studied in preclinical animal models of osteoarthritis, and intraarticular administration (direct injection into the joint) was found to be the most effective route of delivery [58,59]. A recent clinical trial in patients with knee osteoarthritis determined that intraarticular Anakinra, although well tolerated, had no significant clinical benefit compared with placebo [60]. However, other studies have demonstrated the efficacy of intraarticularly injected IL-1 receptor antagonists in reducing postoperative pain and inflammation while improving knee function in patients who underwent the surgical treatment of knee injuries [61,62]. Thus, the use of intraarticular delivery for local antiinflammatory biologic agents remains a promising strategy warranting continued investigation.

***22.2.3.2 Local Administration of Cell-Based Therapies*** The recent FDA approvals of Provenge, an autologous cell-based cancer vaccine against prostate tumors, and Hemacord, a progenitor cell therapy derived from cord blood for the treatment of hematopoietic disorders, are two respective examples in which the systemic dissemination of cellular therapies via IV delivery can be advantageous or essential. However, the majority of cell transplantation therapies, for a variety of diseases and indications, have historically been administered directly at the site of disease, dating back to the development of tissue or organ transplant procedures. This is largely

because the majority of cells, when infused systemically, lack the necessary homing capacity or ability to transmigrate across endothelium in order to reach their intended tissue. Presently, there are two FDA-approved cellular biologic therapies requiring local injection: Laviv and Carticel (refer to Table 22.1). In the case of stem cell–based therapies, many of which are under ongoing research, an additional concern of systemic administration is the potential risk of nonterminally differentiated, tumorigenic cells taking residence in improper anatomical tissues [63,64]. Therefore, local administration is the primary route of delivery for a growing number of stem cell therapies that are now under preclinical or clinical study.

Numerous preclinical studies in stem or progenitor cell therapies for cardiac repair have demonstrated cellular infiltration into damaged myocardial tissue, differentiation into or regeneration of cardiomyocytes, and overall improvements in cardiac function in animal models of ischemic heart disease [65]. Although the IV infusion of autologous mesenchymal stem cells has shown the ability of achieve myocardial engraftment and subsequent therapeutic efficacy in animal models, clinical benefits have yet to be demonstrated in human trials by this injection route, possibly because of the entrapment of cells in the lungs and an inability to access the damaged myocardial tissue [66,67]. On the other hand, a large number of clinical trials are currently ongoing using direct intramyocardial injections or intracoronary vein injections of various stem and progenitor cell populations, and earlier clinical studies of locally administered cell therapies have already demonstrated promising improvements in clinical outcome [65,68,69].

Other examples of stem cell–based therapies for treating highly localized diseases include the recent, well-publicized trials of the first-ever embryonic stem (ES) cell–derived treatments attempted in human patients. The first of these was GRNOPC1 (from Geron) in which oligodendrocytes derived from human ES cells were injected into the spinal cords of patients with spinal cord injuries [70]. The second trial (from Advanced Cell Technology) involved the injection of retinal pigment epithelium cells (also derived from human ES cells) into the eyes of patients with Stargardt's macular dystrophy [71]. ES cell–derived therapies carry an even greater level of risk than adult stem cell or progenitor cell therapies because ES cells possess the highest degree of pluripotency and therefore the greatest likelihood of forming a tumor or teratoma. These examples highlight the unique challenges faced by cell-based treatments, which must balance the ability of cells to engraft into their proper tissue after systemic delivery against the challenge and cost of highly specialized surgical procedures for localized infusion therapy.

### 22.2.4 Oral Administration of Biologics

The oral delivery of therapeutic drugs is highly attractive because of its convenience and ease of administration. Although a vast number of small molecule drugs have been formulated for oral intake and absorption through the GI tract, the successful delivery of biologics such as proteins, peptides, and small interfering (siRNA) has yet to be achieved. The primary difficulties preventing effective oral delivery of biologics include the presence of proteolytic enzymes and the low pH found in the GI

tract, which can cause the degradation of biologics; the low permeability of the epithelial layer and mucosa lining the GI tract, which hinders the absorption of biologics into the bloodstream; and the hydrophilicity and macromolecular size of most biologic agents, which limits their passive diffusion transcellularly through the epithelial layer. Therefore, a variety of strategies have been proposed and studied, predominantly in the preclinical setting, in an attempt to overcome these limitations.

***22.2.4.1 Particle Carriers for the oral Delivery of Biologics*** Microparticle and nanoparticle carriers have been investigated extensively for the encapsulation and oral delivery of proteins for the dual purposes of protecting their cargo from the degradative environment of the GI tract as well as enhancing uptake across the intestinal epithelium. Historically, much of the research into particle-mediated oral delivery has been performed in the context of the development of subunit antigen vaccines [1,72]. Although live-attenuated or killed whole-cell vaccines have shown some success via oral administration (reaching global market approval in the cases of polio, cholera, rotavirus, and others), oral subunit antigen vaccines currently have yet to achieve market approval [72].

It has long been known that whole cells such as bacteria are able to adhere strongly to intestinal epithelium, thereby inducing uptake into gut-associated lymphoid tissue (GALT) and subsequent immune priming for a successful vaccination. Therefore, it was hypothesized that particulate oral delivery of protein or peptide antigens could also be used to improve the uptake of antigens into GALT (relative to soluble antigens administered orally), especially if combined with the use of surface targeting ligands or the presentation of Toll-like receptor (TLR) ligands to mimic whole pathogens [72]. A wide variety of particle systems have been studied for oral vaccine delivery, including lipid-based particles such as liposomes, polymeric particles based on synthetic materials such as poly(lactic-*co*-glycolic acid) (PLGA), and hydrogel particles based on naturally occurring polysaccharides such as alginate or chitosan [1,73,74]. Strategies for improving particle uptake have included the use of specific antibody targeting [75], the incorporation of adhesive bacterial proteins [76], and the use of immune-stimulatory adjuvants such as TLR ligands [77], and enteric coatings have been used to surround microparticles for increased protection against degradation [78–80]. However, despite convincing demonstrations of enhanced uptake into GALT, oral delivery systems for subunit vaccines have yet to achieve sufficient levels of mucosal immune protection in both preclinical and clinical studies compared with the oral administration of whole-cell vaccines [1]. Insufficient protection of the antigen in the GI tract and an inability to sustain release of the antigen after oral administration are likely critical factors responsible for this lack of efficacy.

Similarly, particulate systems have been investigated for the encapsulation and oral administration of biologic therapeutics. For example, there has been a major focus on developing strategies for the oral delivery of insulin, which is one of the most commonly prescribed protein drugs. An effective oral administration of insulin would provide enormous benefits in convenience and quality of life for diabetic patients that currently require frequent needle injections for self-dosing. However,

when administered orally in free (soluble) form, insulin and other protein drugs cannot be effectively absorbed paracellularly from the GI tract because of the highly tight permeability of the intestinal epithelium [81]. Furthermore, even if protein drugs are endocytosed into epithelial mucosal cells at the apical membrane (from the GI tract), there is minimal release or secretion of the drug at the basolateral membrane for absorption into the bloodstream [82,83]. This has prompted the investigation of particle carriers such as PLGA or other polymeric nanoparticles [84], chitosan nanoparticles [85–87], polymeric micelles [89], and others [89,90]. Encapsulation within such carriers can improve the delivery of insulin and other protein drugs by mediating uptake into, and more importantly, translocation through the epithelial mucosal lining [91]. The addition of targeting moieties to the particle surface can further improve the internalization and transcellular passage of drug-loaded particles across the intestinal epithelium [92]. Nevertheless, despite preclinical successes in animal models, the effective oral delivery of proteins via particle carriers remains elusive partly because of the poor loading efficiency of hydrophilic macromolecules into many such particle formulations, the inability of these nanoparticles to maintain colloidal stability in the harsh environment of the GI tract, and the inability to sustain or control drug release.

***22.2.4.2 Co-delivery of Modulatory Agents to Improve Absorption from the Gastrointestinal Tract*** A second general strategy for improving the oral delivery of biologics involves the co-administration of modulatory compounds aimed at either directly enhancing uptake into epithelial cells, increasing the permeability of the epithelial layer (to allow paracellular absorption), or inhibiting proteolytic activity in the GI tract. Using a diverse array of agents such as cell-penetrating peptides, detergent-like molecules, or mucoadhesive polymers, these effects have been demonstrated in both *in vitro* models of epithelial cell layers and *in vivo* animal models.

Cell-penetrating peptides (CPPs) have been widely investigated for intracellular delivery in a variety of applications, including cancer therapy, gene transfection, and drug delivery [90]. For the purpose of oral drug delivery, cell-penetrating peptides such as the TAT peptide, penetratin, and oligoarginine can theoretically enhance uptake by increasing the membrane permeability of epithelial cells in the intestinal lumen. For example, this has been demonstrated for the delivery of insulin and other protein drugs into *in vitro* cultured monolayers of Caco-2 epithelial cells [93,94] or by direct injection into intestinal loops [95–97]. In these studies, the protein drugs and CPPs have been combined either by covalent conjugation or by noncovalent association before delivery. Investigations of the overall absorption efficacy and subsequent bioavailability of the administered biologic after an actual oral delivery in animal models remains ongoing [94].

Another strategy for permeation enhancement involves the co-delivery of detergent-like or lipid-based molecules, such as the salts of fatty acids, pluronic acid, or small molecule hydrophobic compounds [98–101]. These agents can act either by directly increasing the permeability of cell membranes, thus enhancing epithelial cell uptake of the biologic, or by destabilizing the tight junctions between cells in the epithelial layer, thus increasing paracellular absorption of the drug. Another study

demonstrated the use of a toxin (zonula occludens) to reversibly weaken these epithelial cell tight junctions and enhance the absorption of orally administered insulin [102]. However, the nonspecific action of such agents poses the risk of causing severe disruptions to the anatomical GI barrier, which could then lead to significant toxicity because of the unintended passage of GI-resident pathogens or other compounds into the bloodstream [103]. As a potential strategy to mitigate this risk, a recent study described the development of a controlled-release device aimed at optimizing the delivery kinetics of an absorption enhancer (sodium glycocholate) relative to insulin delivery, although it remains to be tested in an *in vivo* model of oral administration [104].

Finally, protease inhibitors have been used in oral co-delivery with protein drugs to combat the effect of proteolytic enzymes present in the GI tract and the epithelial mucosal layer. For example, inhibitory compounds such as camostat mesilate and bacitracin can be simply co-administered with the protein drug of interest [105–108], protease inhibitors can be co-encapsulated with the biologic drug in a carrier [104], or the particle carrier itself can incorporate protease-inhibiting compounds directly in its composition while being loaded with a biologic drug cargo [87]. However, as with the use of permeation enhancers, the nonspecific action of protease inhibitors in the GI tract has the potential for complications, particularly if used at high doses, and as a result, this strategy has not yet achieved clinical success or approval [103]. Therefore, the passive avoidance of proteolytic degradation by using inert, protective nanoparticle carriers may be more likely to reach clinical translation in the future. Overall, despite extensive studies over the past three decades into the oral delivery strategies described here, the promising results observed in preclinical research have yet to develop into successful clinical strategies for oral biologic drug administration.

## 22.3 ALTERNATIVE ROUTES OF ADMINISTRATION

Although traditional routes of administration for biologics have been very successful in the clinic, these routes have limitations. Although it can be the best choice for drug formulation and pharmacokinetic and pharmacodynamic reasons, IV dosing is impractical for repeated or chronic use for non–life-threatening conditions. SC injection is simple and convenient but can have complications of injection site reactions (e.g., up to 70% of patients in the case of IL-1R antagonists) [109], which are often related to mast cell degranulation and can be caused by the solution vehicle, the high concentrations of protein typically administered, or both [30]. Finally, the biology of many diseases and candidate drugs may logically suggest that other sites of administration may be more effective for treatment, such as airway delivery of biologics for treatment of respiratory disorders or transcutaneous delivery of drugs targeting skin infections. Thus, a variety of preclinical and clinical efforts are underway to develop alternative routes of administration in a broad spectrum of biological drug products, and a few of them have already made their way to the market. Another reason for such efforts is the noninvasiveness of some alternative delivery routes for systemic applications.

### 22.3.1 Airway Delivery of Biologics

Airway delivery has frequently been proposed as the most feasible alternative to parenteral injections because of the high permeability of the nasal and pulmonary epithelium [109]. Other advantages include the large surface area, extensive vascularization, thin air–blood barrier, relatively low enzymatic activity, and no first-pass hepatic metabolism, which helps to increase bioavailability while reducing required drug doses and side effects [110–112]. Pulmonary delivery not only enables local delivery of therapeutics targeting respiratory diseases but can also access the systemic circulation where the rapid drug absorption rate can result in plasma drug profiles that sometimes parallel those from IV injections [110,112]. Finally, the noninvasive nature of the airway delivery route also helps increase patient compliance.

In 1993, the first protein administered via inhalation, the recombinant human DNase (Pulmozyme, Genentech, Inc.), was approved by the FDA for the treatment of cystic fibrosis. Today several inhaled insulin products are in development [113–115]. The furthest in development of these formulations is inhaled human insulin powder (Exubera, Pfizer), studied in adult patients with type 1 or type 2 diabetes [114,115] and approved in the United States in 2006 for the treatment of adult patients with diabetes. Unfortunately, a lack of sales led to the removal of Exubera from the market after only about 1 year [116,117]. Clinical trials by other companies (Alkermes with Eli Lilly and Aradigm with Novo Nordisk) were also discontinued for commercial reasons, although Mannkind's Afrezza Technosphere Insulin is currently pending approval by the FDA [116,117]. Other proteins and peptides under study for pulmonary administration in clinical trials include glucagon-like peptide for diabetes mellitus, IFN-$\alpha$ for antitumor therapy, IL-2 for various cancers, and Sargramostin for metastatic cancer and sarcoma [117]. In 2006, the European Medicines Agency granted orphan designation to an inhaled human IL-2 produced by Immunservice GmbH for the treatment of renal cell carcinoma [117].

Pulmonary gene delivery can mediate direct access to lung epithelial cells and correct specific genetic abnormalities in lung diseases such as cystic fibrosis, chronic obstructive pulmonary disease, asthma, and pulmonary fibrosis and possibly for the treatment of lung cancer, pulmonary hypertension, and acute lung injury [118]. Pulmonary delivery offers several advantages over systemic administration, such as improved nucleic acid stability because of lower nuclease activity in the airways than in the serum, enhancing retention in the lungs and reducing the dose required and hence any systemic toxic effects. With the recent advances in RNA interference (RNAi), two of the four siRNA drugs currently in phase II clinical trials are delivered intranasally or by inhalation [119,120].

For vaccination, FluMist (MedImmune, Gaithersburg, MD, USA), a live-attenuated influenza vaccine administered via a nasal spray and other inhaled spray-dried formulations containing whole inactivated virus or split subunit vaccine, have been developed for influenza prevention [121,122]. In the early 1990s, about 4 million children were immunized against measles with a home-built system that incorporated a jet nebulizer from IPI Medical Products (Chicago, IL, USA). Aerosolized vaccine against measles provided a stronger and more durable boosting response

than injection in school-age children and is subject to testing by the World Health Organization in mass immunization campaigns [123,124]. Similarly, an inhaled measles and rubella vaccine [125], a triple vaccine (measles, mumps, and rubella) [126], a dry powder formulation of live-attenuated measles vaccine [127], and inhaled vaccines for protection against inhaled bioterrorism agents such as anthrax and tularemia are under development [128,129].

***22.3.1.1 Barriers to Airway Delivery of Biologics*** The airways possess several features to protect against foreign molecules, including physical or mechanical (epithelial barrier and mucociliary clearance), chemical (enzymes), and immunologic defense mechanisms (macrophages) [130,131]. These must be overcome to ensure efficient delivery of biologics.

*Mucociliary Clearance* Most foreign particulates are efficiently trapped in the mucus layer by steric obstruction or adhesion. The limited permeability of molecules through the mucus barrier leads to their rapid clearance by coordinated movement of cilia that removes mucus from the delivery site toward the pharynx. The ability of the drug to penetrate the mucus barrier depends on particle charge, solubility, lipophilicity, and size [132,133]. As such, strategies to alter drug characteristics and overcome mucociliary clearance include the use of prodrugs as well as mucoadhesive drug delivery systems based on materials such as chitosan and alginate to promote retention and enhance penetration of therapeutic molecules [138].

*Enzymatic Degradation in the Epithelial and Alveolar Lining Fluid* Biologics delivered via the airways are susceptible to chemical degradation by enzymes present in the epithelial and alveolar lining fluid. The proteolytic activity in the epithelial lining fluid presents a major barrier to pulmonary delivery of therapeutic peptides because these compounds are considered to be absorbed primarily by the paracellular route [134,135]. Enzymatic hydrolysis of small natural peptides can be very high, resulting in low bioavailabilities unless they are chemically engineered (blocked) to inhibit peptidases [136]. Notably, as molecular mass increases (leading to formation of tertiary and quaternary structures), peptidase hydrolysis is inhibited, and bioavailabilities of natural proteins are consequently increased [136,137]. Modifications of drug molecules, incorporation of enzymatic inhibitors or the use of carrier particles can also help prevent enzymatic degradation of biological molecules.

*Macrophages* Macrophages in the airways, particularly alveolar macrophages located on the alveolar surface, are known to rapidly engulf foreign particles by phagocytosis as a defense mechanism. Protein therapeutics that are taken up by macrophages are eventually degraded in the phagolysosomes of the cells [138,139]. Clearance by alveolar macrophages has been demonstrated as an important mechanism of elimination of inhaled macromolecules, particularly for moderate-sized to large proteins, after delivery to the lungs and before absorption into the systemic circulation. Depletion of alveolar macrophages by liposome-encapsulated dichloromethylene diphosphonate causes a several-fold enhancement in systemic absorption of IgG

and human chorionic gonadotropin after intratracheal instillation in rats [139]. Molecules such as insulin are formulated either as liquids or in highly water-soluble aerosol particles that dissolve rapidly in the lungs and thereby largely avoid macrophage degradation [140].

*Epithelium and Tight Junctions* Underlying the mucus layer, airway epithelial cells form a tight ciliated barrier connected by tight junctions that blocks fluid flow and control the transport of ions and solutes through the intercellular space [141]. The permeation of hydrophilic substances of high molecular weight and ionic species is limited [142], with the molecular weight cutoff of the tight junctions of alveolar type I cells at 0.6 nm [143]. Toxin molecules and carrier systems based on materials such as chitosan have been proposed to reversibly open tight junctions to enhance adsorption of therapeutic molecules [144,145].

***22.3.1.2 Aerosolization of Biologics*** For biologics to be delivered to the lungs by inhalation, they must be formulated as an aerosol. Aerosol preparations are dispersions or suspensions of solid materials or liquid droplets in a gaseous medium. Drug delivered by aerosol is deposited in the airways by gravitational sedimentation, inertial impaction, and diffusion, where larger particles are deposited by the first two mechanisms in the airways and smaller particles reach the peripheral region of the lungs by diffusion [146]. For distribution throughout the lung, drug particles should be between 1 and 5 μm in diameter; for delivery into the alveolar region, 1 and 3 μm in diameter is optimum. Whereas particles that are too large cannot easily traverse the bronchial network, particles that are too small descend into the deep lungs inefficiently and are more readily lost during exhalation [146].

The efficiency of pulmonary administration is influenced not only by the aerosol formulation but also by the choice of delivery device. Three types of pulmonary delivery devices are commercially available: jet or ultrasonic nebulizers, metered-dose inhalers (MDIs), and dry powder inhalers (DPIs). There are advantages to each based on the stability of the individual molecule and patient needs. Currently, DPIs and nebulizers are being used to disperse aerosol versions of high-molecular-weight proteins. Efforts are increasingly made to adapt biologics for DPs because they frequently are unstable in liquids and costly.

*Nebulizers* Aqueous inhalation formulations typically are administered with the aid of a nebulizer, which breaks up the formulation into inhalable aerosol droplets. Nebulizers deliver relatively large volumes of drug solutions and suspensions for inhalation and are frequently used for drugs that are stable or cannot be easily formulated into MDIs or DPIs. They are also used for drugs such as proteins in which the therapeutic dose is too large for delivery by either MDI or DPI [147].

Nebulizers have evolved from jet nebulizers to ultrasonic nebulizers and, more recently, vibrating mesh nebulizers, offering smaller sizes, improved aerosol performance, and delivery efficiency [148,149]. Jet nebulizers use the motion of compressed gases at high speed through an orifice to produce aerosol droplets in the respirable size range and are most commonly used clinically. Issues include

changes in drug concentration because of evaporation of liquid, which also decreases the liquid temperature. Ultrasonic nebulizers use high-energy ultrasonic waves generated from a piezoelectric crystal to convert liquid into a spray. Ultrasonic nebulizers, however, may be less suited to the delivery of labile biological molecules that may be damaged by direct exposure to the ultrasonic energy during nebulization. Vibrating mesh nebulizers have been introduced in recent years to address the problems associated with their ultrasound and jet predecessors. These nebulizers work by using a piezoelectric crystal with a lower frequency to vibrate a plate or mesh in contact with the liquid, thus avoiding the direct transfer of ultrasound energy to the solution. This approach typically generates a low-viscosity aerosol with small size particles that deliver the drug to the lung in a highly efficient manner, resulting in a substantial decrease in the dose required. They have been successfully used to aerosolize peptides and proteins such as insulin as well as DNA fragments [150].

Nebulizers have been used for the pulmonary delivery of proteins in the past decade but have not proven 100% successful to date. The shear force generated during nebulization can lead to fragmentation of biomolecules [151]. Furthermore, during nebulization, only a small fraction of the energy available in the nebulizer is used to generate the new surface necessary in the production of droplets. The excess energy is converted to heat, causing the temperature of the liquid within the nebulizers to increase; this heat generation may cause chemical degradation of proteins [152]. The viscosity of the solution affects how readily it can be nebulized, so nebulizers may not be useful for dispersing viscous formulations. For instance, because of its viscosity, the concentration of DNA that can be readily nebulized is less than 5 μg/ml. Nebulization of solute and adhesion of DNA to plastic surfaces results in less than 10% of the DNA in a nebulizer cup's being emitted from the device [153,154].

*Metered-Dose Inhalers* In MDIs, the active substance is suspended or solubilized in a propellant formulation, which contains at least one liquefied gas in a pressurized canister that is sealed with a metering valve. Actuation through the metering valve causes rapid expansion of the propellant, generating aerosol droplets to deliver a metered dose of the medication, which is directed by a suitable adaptor or actuator for administration via oral or nasal inhalation [166].

The main concern in the administration of biologics with MDIs is the maintenance of the conformational stability of proteins in hydrofluoroalkane (HFA) propellants. Using Raman spectroscopy, Quinn et al. demonstrated the structural integrity of lysozyme was maintained in HFA propellants [155]. Kos Pharmaceuticals has successfully completed a 4-week phase IIa human clinical trial evaluating MDI-delivered inhaled insulin therapy for patients with type 2 diabetes. The results of this trial showed that inhaled insulin is comparable to the market-leading injectable insulin in controlling blood glucose levels while also reducing blood lipids such as low-density lipoprotein cholesterol and triglycerides. Kos's inhaled insulin had also demonstrated bioavailability of up to 23% in previous phase I trial [156]. Thus, MDI administration may be a route of interest for further development in the delivery of biologics.

*Dry Powder Inhalers* DPIs are aerosol systems in which drugs are inhaled as clouds of fine particles. The drug is either preloaded in an inhalation device or prefilled in the form of hard capsules or foil blister discs that are loaded into a device before use. DPIs present some advantages over nebulizers and MDIs, especially for the administration of peptide and protein therapeutics to the lungs because of improved stability of formulations as a result of the dry state [157–159].

Size control, which impacts drug distribution, can pose a significant challenge with dry powder formulations, given that the properties of powders can differ widely because of variances in chemical composition and morphology of individual particles. This is often further compounded by the hygroscopic nature of many powders, which tend to absorb moisture leading to agglomeration: Particle size can still be altered during transit in the humid atmosphere of the respiratory tract. As a result of strong interparticle forces, drug delivery by DPI is also highly dependent on respiratory flow rate, which varies greatly [160]. Much research has been done to address this problem. Beyond the use of surfactants to elevate the activation energy of agglomeration by adding electrostatic or steric barriers between particles [161,162], drug nanoparticles are also designed to reduce the interparticle attraction forces and to improve the DPI performance by blending with carrier materials, forming Trojan particles or controlled nanoparticle agglomerates [160,163].

Despite these problems, many proteins have been successfully formulated as DPIs. Chan et al. prepared powders of recombinant human deoxyribonuclease (rhDNase) alone and with sodium chloride (NaCl) by spray drying where they observed better dispersal properties with the later [164]. Lucas et al. evaluated the use of carrier-based dry powder aerosols for pulmonary delivery of bovine serum albumin (BSA) and saw improved inhalation performance with mixtures prepared using BSA–maltodextrin and lactose [165]. It was concluded that fine-particle excipients can be used to improve the performance of carrier-based protein dry powder aerosols.

***22.3.1.3 Intranasal Delivery of Biologics*** Intranasal delivery has grown increasingly attractive as a noninvasive delivery route for a diverse range of therapeutic agents for local, systemic, and central nervous system (CNS) action. Targets for intranasal administration include compounds such as peptides, proteins, and polar drugs with low stability in GI fluids, poor intestinal absorption, or extensive hepatic first-pass elimination [166]. Nasal delivery also provides a way to bypass the BBB for direct drug delivery to the CNS in addition to being considered for the administration of vaccines [166,167]. Intranasal administration also offers several practical advantages both from the perspective of patients (painlessness and ease of delivery) and pharmaceutical companies (sterilization of nasal preparations is not required) [168,169].

However, some limitations should be considered when formulating biologics for intranasal delivery. First, in addition to the physicochemical properties of drugs and characteristics of their formulations, a variety of physiologic and pathological conditions related to the nasal mucosa may compromise the extent of nasal drug absorption and therapy efficacy [166,168,170]. Second the low volume of the nasal cavity restricts the volume administered to about 100 to 150 μl [170]. Nevertheless, strategies to

**TABLE 22.2 Representative Biologic Therapies Administered by Intranasal Route**

| Drug Name | Biological Agent | Indications |
|---|---|---|
| | *A. Marketed* | |
| Miacalcin | Calcitonin | Postmenopausal osteoporosis |
| Desmospray | Desmopressin | Diabetes insipidus |
| Suprecur | Buserelin | Prostate cancer |
| Syntocinon | Oxytocin | Labor induction, lactation stimulation |
| Synarel | Nafarelin | Endometriosis |
| Flu Mist | Live attenuated influenza virus | Flu prevention |
| | *B. In Clinical Trials* | |
| | Human growth hormone | Growth hormone deficiency |
| | Insulin | Diabetes mellitus |
| | Adenovirus-vectored influenza | Flu prevention |
| | Proteosome-influenza | Flu prevention |
| | Group B meningococcal native outer membrane vesicle | Meningococcal meningitis prevention |
| | Live-attenuated respiratory syncytial virus | Respiratory disease prevention |
| | Live attenuated parainfluenza 3 virus | Respiratory disease prevention |

overcome these drawbacks have led to successfully marketed intranasal biologic drugs and vaccines and others in clinical trials as outlined in Table 22.2 [116,171,172].

*Systemic Delivery* Intranasal administration is an effective alternative route to systematically deliver drugs that are administered conventionally via oral or parenteral routes. Furthermore, relative to multiple parenteral applications, repetitive intranasal administration is more practical for chronic applications, especially when oral delivery results in insufficient drug bioavailability, which is often the case for biologics such as peptides and protein with poor oral absorption. However, for currently marketed intranasal peptide and protein products, the formulations generally do not include permeation enhancers, resulting in relatively low bioavailability because of their relatively high molecular weight [181]. The bioavailability of these macromolecules can be improved by using permeation enhancers.

*Nasal Vaccine Delivery* Most pathogens invade the body through mucosal surfaces. Among other mucosal sites, nasal delivery is especially attractive for immunization because the nasal epithelium is characterized by reasonable permeability, low enzymatic activity, and the presence of a significant number of immunocompetent cells. Relative to parenteral routes, nasal vaccination is also beneficial because it is able to induce both mucosal (sIgA) and systemic (IgG) immune responses. In the upper airways, systemic and local immunologic responses are mainly mediated by the nasal-associated lymphoid tissue (NALT, also known as Waldeyer's ring in humans) situated

underneath the nasal epithelium, which is composed of clusters of dendritic cells, T cells, and B cells [173]. Notably, after nasal immunization, secretory immunoglobulin A can also be detected in other mucosal secretions (e.g., vaginal mucosa), which may be important against pathogens transmitted through other mucosal sites, such as human immunodeficiency virus [174] and hepatitis B virus [175]. Despite these encouraging characteristics, intranasal delivery of free antigens alone may not elicit an immune response in the absence of an effective adjuvant. Effective nasal immunization thus requires an effective antigen or a potent mucosal adjuvant or carrier. To enhance potency, immunostimulants such as TLR ligands, toxin-based adjuvants, or cytokines can be co-delivered [173]. In addition, encapsulation of antigens into bioadhesive particles can further improve nasal vaccine administration. These antigen-loaded particles can also incorporate targeting ligands, adjuvants, or endosomal escape mediators to help generate and enhance immunity [176,197].

*Central Nervous System Delivery* Improved delivery to the brain via the nasal route has been reported for therapeutic hormones, peptides, and proteins [177–181]. However, it should be noted that there are also cases in which evidence was found lacking for preferential delivery to the brain via intranasal delivery [182–184]. Although the clinical potential of this delivery route is still the subject of controversial debates, there is considerable interest in exploring the route to deliver peptide and protein for treatment of common intracerebral diseases such as Alzheimer's disease [185] and obesity [186].

*Strategies to Increase Nasal Drug Absorption* The bioavailability of nasally administered drugs is generally limited by low drug solubility, rapid enzymatic degradation in the nasal cavity, poor membrane penetration, and rapid mucociliary clearance. As such, various strategies have been devised to overcome these limitations, including the use of prodrugs, enzymatic inhibitors, absorption enhancers, development of mucoadhesive delivery systems, and new pharmaceutical formulations.

Prodrugs can be used to modify a compound's lipophilicity, improving solubility and ultimately increasing its transport across a biological membrane [209]. In addition, the potential of prodrugs to protect peptides from nasal enzymatic degradation has been suggested for increasing the bioavailability of intranasally administered peptides and proteins [168,170]. Enzymatic inhibition can also be achieved using certain absorption enhancers. For example, disodium ethylenediaminetetraacetate has been shown to reduce enzymatic degradation of a β sheet-breaker peptide used for the treatment of Alzheimer's disease [187]. Strategies to modify the cargo molecule to confer resistance against enzymatic degradation have also been attempted to increase the nasal bioavailability of calcitonins [188,189]. Such strategies, however, would warrant toxicologic studies to evaluate the safety of the modified molecules.

Mucociliary clearance is a major limiting factor for nasal delivery because it reduces the time available for drug absorption. To improve drug absorption by prolonging the contact time between drug and nasal mucosa, a range of mucoadhesive drug delivery systems based on materials such as chitosan and alginate have been developed in preclinical studies, some of which can also open epithelial tight

junctions and inhibit proteolytic enzymes [190]. Nasal formulations containing liposomes, microspheres, and nanoparticles have also been developed extensively for intranasal drug delivery. These systems can contain, besides the drug, enzymatic inhibitors, nasal absorption enhancers, or mucoadhesive polymers, to improve the stability, membrane permeation, and retention time in the nasal cavity. Liposomes were found to enhance nasal absorption of peptides such as insulin and calcitonin by increasing their membrane penetration [191,192]. Wang et al. [193] have investigated aminated gelatin microspheres as a nasal drug delivery system for insulin and observed a significant hypoglycemic effect on intranasal administration as a dry powder to rats. Studies have also suggested that nanoparticle systems may be ideally suited for the delivery of nasal vaccines [194–196].

### 22.3.2 Transcutaneous Delivery of Biologics

A wide range of biologics such as protein-, peptide-, and DNA-based drugs and vaccines are poorly suited to oral delivery because of their high degree of first-pass metabolism in the liver. The transdermal route has the potential to overcome this limitation and provide an efficient way of administering such molecules. The skin represents the largest and most easily accessible organ of the human body and provides a convenient and patient-friendly interface for drug administration. In addition, the transcutaneous route offers promise for achieving sustained and controlled drug delivery. Transcutaneous vaccine delivery could improve immune responses by targeting delivery to immunogenic Langerhans cells in the skin and has attracted increasing interest.

Advances in transdermal delivery systems have been categorized into three generations of development [197]. First-generation transdermal delivery systems have seen a steady increase in clinical use for delivery of drugs that are permissible to the skin via passive diffusion. Second-generation delivery systems using chemical enhancers, noncavitational ultrasonography, and iontophoresis to enhance permeability and drive transcutaneous transport have also led to clinical products. Third-generation delivery systems using microneedles, thermal ablation, microdermabrasion, electroporation, and cavitational ultrasonography to circumvent the barrier presented by the stratum corneum are being actively pursued. Examples of transcutaneous delivery of biologics in clinical development include human growth hormone via thermal ablation (phase 1, TransPharma Medical Teva Pharmaceuticals, Lod, Israel/Petach Tikva, Israel), insulin using thermal ablation (phase 1, Altea Therapeutics, Atlanta, GA, USA) or vesicular carriers (phase 2, Phosphagenics, Melbourne, Australia), parathyroid hormone (PTH) with microneedles (phase 2, Zosano, Fremont, CA, USA), as well as a microneedle-based influenza vaccine (completion of phase 3 clinical trials and submission for registration in Europe by Sanofi Pasteur, Paris, France, and Becton Dickinson, Franklin Lakes, NJ, USA) [197].

***22.3.2.1 Barriers to Transcutaneous Drug Delivery*** Despite representing an attractive target for drug delivery, the functional properties of the skin that make

it an excellent barrier also serve to limit the access of drugs and vaccines into and across the epidermis. The skin is especially adept at keeping out high-molecular-weight compounds, rendering it unrealistic for therapeutic levels of drugs and vaccines to be attained by mere passive absorption. Therefore, an understanding of the barrier properties of the skin will complement the design of strategies to overcome this barrier safely and reversibly in order for transcutaneous delivery to achieve its anticipated potential for the administration of biological products. The skin is composed of several anatomically distinct layers. The stratum corneum, composed of lipids and dead epidermal cells (corneocytes), is the outermost superficial layer (10–20 μm thick) and provides the principal barrier to the percutaneous absorption of exogenous compounds as well as to water loss [198]. The corneocytes are flat anucleated squamous cells composed mainly of cross-linked keratin surrounded by a cell envelope composed of cross-linked proteins and a covalently bound lipid envelope [198]. The stratum corneum lipids are composed primarily of ceramides, cholesterol, and fatty acids that are assembled into multilamellar bilayers, resulting in a very densely packed matrix that serves the primary barrier function [200]. Underlying the stratum corneum is the viable epidermis (50–100 μm thick), which is responsible for regeneration of the stratum corneum. The dermis (1–2 mm thick) lies directly adjacent to the epidermis and provides mechanical support for the skin. A rich capillary bed for systemic drug absorption also sits just below the dermal–epidermal junction.

Molecules may cross the stratum corneum via an intercellular or a transcellular route. Moreover, transport across the stratum corneum and even the epidermis can also occur through shunt pathways such as hair follicles, sebaceous glands, and sweat ducts. Transcutaneous transport is largely controlled by stratum corneum lipid bilayers and is highly anisotropic and size dependent [201]. Because of the impermeable character of the cornified layer, the major route of penetration resides in the tortuous pathway around the corneocytes, where hydrophilic molecules travel through the lipid head group regions and lipophilic molecules travel through the lipid tails regions. Transport between bilayers can also occur at bilayer–bilayer interfaces or other sites of structural disorganization. Cutaneous penetration of hydrophilic substances is limited by the convoluted intercellular space as well as the hydrophobicity of the lipidic components present in the stratum corneum, which imposes structural and solubility constraints for solution and diffusion within stratum corneum lipid bilayers. For systemic delivery, after its transport through the stratum corneum, the drug still need to partition into the aqueous epidermis and finally into the capillary network of the dermis. Hence, a transcutaneous drug candidate must possess both lipophilic and hydrophilic tissue spaces. Molecules too hydrophobic will fail to partition into the SC, and molecules too lipophilic will encounter difficulties in moving through the subsequent aqueous layer in the epidermis [202].

***22.3.2.2 Transdermal Patches*** Despite the significant barrier properties of skin, it was found that small lipophilic drugs exhibit significant permeability, which led to the development of transdermal patches in the 1970s. Today there exist a number of transdermal patches for drugs such as clonidine, fentanyl, lidocaine, nicotine,

nitroglycerin, oestradiol, oxybutynin, scopolamine, and testosterone, as well as combination patches for contraception and hormone replacement [203]. For the delivery of biologics, patches are currently in development for transcutaneous immunization against influenza in elderly and travelers' diarrhea (phase II clinical trial, Iomai Corporation) and various other diseases (EasyVax, Vaxin, Inc.) [204,205].

***22.3.2.3 Penetration Enhancers*** To circumvent the barrier imposed by the skin to transcutaneous delivery of biologics, a wide range of penetration enhancers have been investigated for enhancing transcutaneous penetration. Chemical penetration enhancers can increase skin permeability by various mechanisms, including enhancing solubility, increasing partitioning into the stratum corneum, opening dense protein structure, fluidizing the crystalline structure of stratum corneum, and causing dissolution of stratum corneum lipids [206,207]. Many effective chemical enhancers disrupt the highly ordered bilayer structures of the intracellular lipids found in stratum corneum by inserting amphiphilic molecules into these bilayers to disorganize molecular packing or by extracting lipids using solvents and surfactants to create nanosized lipid-packing defects. Chemical enhancers help increase skin permeability and provide an additional driving force for transport across skin by increasing drug partitioning into the skin, thereby increasing the concentration gradient in the skin driving diffusion of molecules farther into the skin. However, increased permeation enhancement typically correlates with increased skin irritation, and the difficulty of localizing their effects to the stratum corneum to avoid irritation or toxicity to living cells in the deeper skin has largely constrained their application.

Decades of extensive research has yielded several different classes of penetration enhancers, including surfactants, fatty acids and esters, terpenes, and solvents [208]. Ethanol and propylene glycol are often used as solubilizers and can extract lipids in the stratum corneum to facilitate permeation. Oleic acid works by accumulating in the stratum corneum and inducing fluidization and phase separation within the lipid membrane [209]. Surfactants are potent transport enhancers by virtue of their ability to solubilize or extract lipids and denature keratin. Besides off-the-shelf compounds, attempts have also been made to design and synthesize novel chemical penetration enhancers such as lauracapram (Azone) [210,211].

Combinations of chemical enhancers offer further new opportunities in transcutaneous formulations to increase both safety and efficacy. In addition to increasing transcutaneous transport in a synergistic manner, combination of enhancers can also reduce the required dose of each enhancer, making it possible to achieve increased skin permeability in the stratum corneum while avoiding irritation in deeper tissue. However, the rational design of enhancer combinations is limited by the lack of mechanistic information on the interactions between individual chemical enhancers and the stratum corneum. This bottleneck has been addressed with high-throughput methods for screening transdermal formulations to discover previously unknown enhancer mixtures [212]. Dramatically increased enhancement with low skin irritation potential was found, for example, for a combination of sodium laureth sulfate (an anionic surfactant) and phenyl piperazine (a compound with aromatic nitrogen) at concentrations of 0.35% and 0.15% by weight, respectively, in a 1:1 mixture of ethanol

and phosphate-buffered saline. *In vitro* screening results were validated with *in vivo* delivery of a peptide (leuprolide acetate) to hairless rats. These results suggest that combinations of chemical enhancers may succeed for delivery of macromolecules where individual enhancers have generally failed. Such an approach is currently being pursued in industry.

More recently, peptides have been examined as enhancers of skin permeability. Although lipophilic derivatives of peptides have been reported to exhibit increased skin permeability [213], co-delivery of certain peptide sequences has also been shown to enhance protein and siRNA delivery [214,215]. In one such study, phage display was used to screen a library of peptides, which yielded a synthetic peptide sequence that, when coadministered with the cargo, increased transdermal delivery of insulin in diabetic rats [216]. Further analysis suggested that the main pathway of transport was via hair follicles. Another study has shown that a natural pore-forming peptide, magainin, increases skin permeability by targeting bilayer disruption in stratum corneum lipids but not in deeper tissue [217]. The magainin peptide was only effective when applied in combination with a surfactant chemical enhancer, which served a dual purpose of increasing skin permeability to the drug as well as magainin. In addition to peptides, trypsin has also been shown to enhance the transcutaneous delivery of insulin [218].

Colloidal carriers such as emulsions, micelles, dendrimers, liposomes, and deformable vesicles have also been used as chemical penetration enhancers with supramolecular structure that can enhance skin permeability, drug solubilization in the formulation, and drug partitioning into the skin [219–221]. Their supramolecular size generally precludes penetration into deeper tissues and thereby localizes the effects to the stratum corneum. For example, the incorporation of surfactants in these carriers can fluidize the lipid layers in the skin and allow for the formation of depots in the stratum corneum for prolonged effect. In the case of deformable vesicles, their flexible nature has been suggested to enable them to squeeze through pores in the skin. A highly deformable liposome formulation is currently in clinical trials for insulin delivery [197]. Recently, the percutaneous delivery of protein drugs mediated by co-administrating with gold nanoparticles was also reported [222]. This method was then used toward a transcutaneous vaccine study in which immune response in mice was elicited by topically co-administrating antigens with gold nanoparticles.

***22.3.2.4 Ballistic Intradermal Delivery*** After a rise and fall in popularity in the 1950s, high-velocity jet injectors are receiving renewed interest for controlled, needle-free injection of drug solutions or particles across the skin and into deeper tissue. Current commercial jet injectors use compressed gas to generate high-velocity micron-sized ballistic droplets or particles that impinge on and penetrate the skin barrier. Solid particles such as DNA-coated gold particle vaccines [223] or droplets such as insulin solution [224] can be delivered into the epidermis to target particular cells or into deeper dermis for subsequent absorption into blood capillaries. Ballistic delivery using jet injectors combines the advantages of transdermal and parenteral drug delivery methods, allowing direct access into the skin tissue while alleviating the issues of patient phobia, injury, cross-contamination, and waste disposal associated with the use of needles.

Jet injection is the first and only approved needle-free protein delivery system for transcutaneous delivery to date. Liquid jet injectors have been used to deliver several macromolecules, including vaccines [225], insulin [224], growth hormones [226], erythropoietin [227], and INF [228]. Insulin delivery by jet injections has been shown to be as effective as needles in the control of blood glucose levels [229,230]. They represent the first commercial needle-free method for insulin delivery (Antares Vision, Choice, Antares, previously Mediject) and the only such method until the recent FDA approval of inhaled insulin. The first growth hormone injector was also introduced by the same company in Europe in 1994. Increased and earlier maximum blood concentrations were found after jet injection of recombinant human growth hormone compared with needle injections [231]. Other macromolecules, such as low-molecular-weight heparin [232] for treatment of deep vein thrombosis and botulinum toxin [233] for the treatment of plantar hyperhidrosis have also been delivered by jet injections in humans. Liquid jet injections were successfully adopted for immunizing humans using vaccines against a large number of diseases, including measles, smallpox, cholera, hepatitis B, influenza, and polio [234]. However, their usage decreased drastically after evidence of contamination originating from blood and splashed liquid in the multiuse injectors was discovered [235]. This can be avoided by the development of single-use, disposable jet injectors. Currently, jet injections of liquids are being pursued for protein, DNA, and live-vectored vaccines by BioJect [236].

*DNA Vaccine Delivery via Gold Particles* The skin can function as an effective induction site for both mucosal and systemic immune responses. Indeed, the administration of vaccines to the skin by ballistic delivery has been shown to induce immune responses in both blood and mucosal tissues [237,238]. DNA can be delivered by jet injectors in a solid form via precipitation onto gold particles (precipitation occurs before delivery), which confers greater stability of DNA relative to liquid formulations and can, in some cases, even allows for the stable storage of DNA at room temperature and deployment without a cold chain. The use of jet injectors to propel particles coated with antigen-encoding DNA plasmids into skin is of great interest for DNA-based vaccination. This is particularly motivated by the immune competency of skin tissue, attributed to the presence of antigen-presenting cells (APCs) such as Langerhans cells. Ballistic delivery can be used to directly transfect APCs, which can then present the translated antigen directly to the immune system. Antigen can also be expressed and secreted by transfected keratinocytes and taken up by resident APCs through the exogenous antigen presentation pathway. Numerous past studies demonstrate that such particle-mediated DNA vaccination induces protective immune responses both in preclinical studies in animal models and clinical trials [239–244]. More recently, a phase I clinical trial was conducted to evaluate a monovalent influenza DNA vaccine containing the HA gene from A/Panama/2007 /99 delivered by particle-mediated epidermal delivery [245]. Treatment-related reactions in patients were mild to moderate and included skin reactions at the vaccine site. These results provided a preliminary indication of the safety and immunogenicity of a prototype epidermal DNA vaccine for influenza. Development of representative annual and avian influenza vaccines is now underway. Other vaccines in clinical trials include biolistic microparticle injection

(PowderMed) for HIV (phase I) and herpes simplex type 2 (HSV2, phase I) as well as a cancer vaccine (phase I) [236].

***22.3.2.5 Ultrasound-Mediated Transdermal Delivery*** Ultrasonic waves at various frequencies in the range of 20 kHz to 16 MHz have been used to enhance skin permeability and facilitate transcutaneous drug delivery, commonly known as sonophoresis. The use of a therapeutic and high frequencies of ultrasound ($\geq$0.7 MHz) for sonophoresis dates back to as early as the 1950s, but low-frequency sonophoresis (20–100 kHz) has only been explored more recently during the past two decades since greater penetration enhancement effect was observed at low frequencies. Although they both use ultrasound to increase the skin penetration of permeants, the associated mechanisms by which they mediate transcutaneous delivery are distinctly different.

Ultrasound-mediated enhancement of transcutaneous transport is thought to be mediated by a combination of thermal and mechanical alterations within the skin tissue. An increase in temperature due to absorption of ultrasound by the skin can increase skin permeability by (1) increasing the kinetic energy and diffusivity of drug compounds, (2) dilating points of entry of the skin (e.g., hair follicles and sweat glands), (3) facilitating drug absorption, and (4) enhancing circulation of blood in the treated area (in *in vivo* experiments) [246,247]. However, the contribution caused by thermal effects is likely to be insignificant in real clinical settings because any thermal effects will have to be minimized to avoid potential damage to the skin tissue. Beyond the elevation of skin temperature, ultrasound is also reported to induce cavitational effects caused by the formation, oscillation, and collapse of gaseous cavities in or near the skin [248]. Specifically, collapse of cavitation bubbles near the stratum corneum is hypothesized to disrupt its structure because of cavitation-generated shock waves or microjets and was determined to be primarily responsible for the efficacy of sonophoresis. In low-frequency sonophoresis (LFS), the primary mechanism of enhancement has been shown to be transient acoustic cavitation above the skin surface, usually occurring in the coupling medium (the liquid present between the ultrasound transducer and the skin). In high-frequency sonophoresis (HFS), cavitation within the skin, either in skin appendages or at locations near the keratinocytes of the stratum corneum, is the main mechanism of skin permeability enhancement [248], although other mechanisms may play more minor roles. Although lower frequencies induce greater enhancements, the transport at low frequencies was found to be localized to discrete regions termed localized *transport pathways* [249] because of the heterogeneous occurrence of cavitation.

In general, HFS is more effective for enhancing the penetration of low-molecular-weight compounds, such as nonsteroidal antiinflammatory drugs and topical steroids into the skin. HFS is also more readily tested in human trials because of its long track record of safety and use in patients for physical therapy. Conversely, LFS has displayed a greater capacity to deliver high-molecular-weight compounds, including proteins, hormones, vaccines, and nanoparticles. However, clinical uses of LFS are relatively rare, with only a few current applications in patients because of the lack of historical precedence of safety. Examples of biological molecules delivered transcutaneously by the use of LFS are summarized in Table 22.3 [250].

**TABLE 22.3 Representative Biological Molecules Delivered Transcutaneously with Low-Frequency Sonophoresis**

| Molecule | Skin model | |
|---|---|---|
| | *In Vitro* | *In Vivo* |
| Bovine serum albumin | Rat full-thickness skin | Rat |
| Erythropoietin | Human heat-stripped skin | Rat |
| Heparin | Pig full-thickness skin | Mouse, rat, rabbit, pig |
| Insulin | Human full-thickness skin, human heat-stripped skin | Mouse |
| Interferon-γ | | |
| Oligonucleotides | Human full-thickness skin | |
| Tetanus toxoid | Pig full-thickness skin | |

Clinical studies have also been performed on transdermal insulin delivery. Glucose-clamp studies in type I diabetic volunteers showed that therapeutic insulin doses can be delivered across ultrasonically permeabilized skin [251]. Ultrasound skin permeation was accomplished using the SonoPrep skin permeation device (Sontra Medical Corp.) which delivers ultrasound at 55 kHz to the skin through an aqueous medium that consists of a phosphate buffered saline solution and 1% sodium lauryl sulfate.

***22.3.2.6 Microneedles*** In the past decade, microneedles have been explored as a way to facilitate transcutaneous delivery of biologics by piercing through the stratum corneum barrier and directly creating transient delivery channels in the skin without stimulating underlying pain nerves. Microneedles can be hollow, similar to traditional hypodermic needles but fabricated on the micro scale, or solid structures coated with drugs [252,253]. They are generally several hundred microns in diameter and range from 100 to 1000 μm in length. Microneedles have been fabricated with various materials such as metals, silicon, polymers, and glass. Notably, microneedles can be manufactured at lower cost using biodegradable polymers that will dissolve in the skin over time, thus circumventing the issues of breakage in skin and the generation of biohazardous sharp medical waste [254–256]. Solid and hollow microneedles have been used as a pretreatment to create micron-sized holes in the skin and have been shown to increase the transport of a variety of small molecules, proteins, and nanoparticles [257]. Alternatively, drug formulations have been coated on or encapsulated within microneedles for rapid or controlled release of peptides, oligonucleotides, plasmid DNA, virus particles, and nanoparticles upon insertion in the skin. Arrays of hollow needles can also be fabricated to flow drugs into the skin using simple diffusion or a pump system and have been used to deliver insulin and vaccines by infusion [257].

Recently, Harvey et al. [258] reported on the pharmacokinetics and pharmacodynamics for microneedle-based intradermal delivery of several classes of approved protein drugs compared with standard SC administration in the swine model using hollow stainless steel microneedles. Delivery of proteins using microneedles resulted in faster systemic availability and increased maximal drug concentration over SC

delivery for all proteins tested. The same group has previously used microneedles to administer numerous vaccines in preclinical models [259–264], and these devices have also progressed through phase I to III clinical trials for influenza vaccines [265–268] with product licensure obtained in Europe [269].

Phase 1 and 2 clinical trials were also recently conducted by Zosano Pharma (formerly Macroflux, ALZA Corp) to evaluate microneedle-based delivery of PTH for treatment of osteoporosis, their lead product candidate in development [270]. The studies suggested that their microneedle patch system was able to deliver a consistent and therapeutically relevant PTH pharmacokinetic profile. Based on encouraging phase 2 safety and efficacy data, the program is advancing into a pivotal phase 3 clinical study. More recently, the same delivery system was also tested for the delivery of erythropoietin in rats (Fig. 22.2) [271]. Previous clinical and preclinical studies have

**FIGURE 22.2** Example of a transdermal microneedle patch delivery system: (a) ZP-patch and applicator (Zosano Pharma, Inc.). (b) Five-$cm^2$ adhesive patch with titanium microneedle array (2 $cm^2$) in applicator ring. (c) 90× magnification of erythropoietin (EPO)-coated microneedles, EPO coated at 3000 IU (30 μg)/3 $cm^2$ array. (d) Front view of an individual EPO-coated microneedle (400× magnification). The length of each microneedle is 215 μm; the thickness is 25 μm; and the length and the width of the microneedle arrowhead are 100 and 115 μm, respectively, with a tip angle of 60 degrees. The microneedle shaft is 115 μm long and 65 μm wide [271].

also demonstrated the capability of their drug-coated microneedle patch technology to deliver peptides, recombinant proteins, and vaccine antigen [272–275].

## 22.4 SUMMARY AND OUTLOOK

The steadily increasing fraction of newly approved drugs that are biologics provides a strong motivation for continued development of new and improved methods and routes of administration to obtain greater efficacy and ease of administration with reduced side effects. Traditional methods of administration via IV or SC injection remain the approved ones for the majority of approved biologics, but diverse preclinical and clinical efforts and recent successfully licensed products making use of alternative routes will likely continue to become more prevalent in the coming few years. Promising technologies include the use of recombinant hyaluronidases to facilitate pain-free large-volume SC injections, the development of diverse methods for transcutaneous drug delivery (e.g., ultrasound, jet injectors, and microneedles), and the successful development of aerosol formulations of protein drugs for pulmonary delivery.

Challenges still remain that limit the efficacy of biologics relative to small molecule drugs. Efficient oral delivery of peptide and protein drugs remains a holy grail of drug development, but general and robust strategies remain elusive. As discussed in this chapter, drug delivery materials such as polymeric and lipid nanoparticles or microparticles can be used to encapsulate and protect biologics from the degradative environment of the GI tract, but these particulate drug carriers are inefficiently absorbed across the gut epithelial lining and are rapidly cleared from the digestive tract, limiting uptake of the drug cargo into the tissues. Efforts to target encapsulated drug cargos to the gut epithelium (e.g., via ligands that bind to target receptors on the epithelium) are still in early preclinical stages, and the ability of such approaches to substantially improve oral delivery efficiencies of biologics remains to be proven. Likewise, pulmonary delivery of biologics has reached the stage of licensed drug approvals, but the efficiency of drug delivery by this route may still be improved, and the long-term safety of drug administration to the pulmonary tissues will only become clear with clinical experience over time. The failure of inhaled insulin to attract a viable patient population also serves as cautionary tale for the development of alternative routes of administration. New methods of drug administration will likely need to offer substantial therapeutic gains, ease of use, or lowered side effects to gain widespread acceptance. However, ongoing innovation in the fields of pharmaceutical sciences and drug development suggest that advanced methods for biologics delivery will continue to evolve and enhance the well-being of patients while improving patient compliance.

## ACKNOWLEDGMENTS

This work was supported in part by the Ragon Institute of MIT, MGH, and Harvard University; the Gates Foundation, the NIH (AI095109 and AI091693); and the
